Preface

This lab manual is designed to accompany the textbook *Foundations of Applied Mathematics Volume 1: Mathematical Analysis* by Humpherys, Jarvis and Evans. The labs focus mainly on important numerical linear algebra algorithms, with applications to images, networks, and data science. The reader should be familiar with Python [VD10] and its NumPy [Oli06, ADH⁺01, Oli07] and Matplotlib [Hun07] packages before attempting these labs. See the Python Essentials manual for introductions to these topics.

Introduction to GitHub

Lab Objective: *Git is a version control system that helps you manage changes to your code over time. It allows you to keep track of different versions of your code, collaborate with others, and revert changes if necessary. In ACME, Git will allow the Lab Assistants to see and grade your code. In this mini-lab you will learn how to successfully save your code to a GitHub repository.*

NOTE

Before we begin, it's important to note that you don't need to complete before you start ACME. The beginning of this program can be overwhelming and this lab is written to be a helpful resource, not your first deadline.

You'll be using Git starting on day 1 so having some intuition about it is helpful, but you DO NOT need a complete understanding of it in order to be successful. This is especially true for the 'Merge Conflict' section of this explanation. You will undoubtedly encounter merge conflicts during your time in ACME and later in your future career, but you can always come back and reference this lab when that happens.

That being said, completing the lab will be helpful, but in the management of your stress during the start of this intensive program, this lab can certainly be something that you put on the backburner and come back to later.

Before you begin this lab, you should have already gone through the Getting Started tutorials. Specifically:

- The course materials should be downloaded and stored in an accessible place on your computer
- VSCode (or another code editor) should be installed and set up on your computer
- You should have created a GitHub account with repositories for Volume 1 and Volume 2
- Python should be installed on your computer

If you have missed any of these steps, stop here and refer back to the Getting Started pdf and the accompanying tutorial videos.

Next, we need to introduce you to a version control framework called Git. We use Git in order to easily have access to your completed labs so the TA's can grade them. Apart from making grading easier, Git is also a tool used almost anywhere you go in industry. Thus, rather than think of this as a tutorial, think of it as the beginning of your education as an ACME major.

1.1 Git

Git is used in industry to facilitate the development of large projects that have many contributors. To illustrate the usefulness of Git, we'll employ a science fiction analogy.

Imagine two people are building a car in the future. One is named Tokyo, the other Brazil, and both live in the countries they're named after (So they live very far away from each other). In this analogy futuristic technology exists so that neither Tokyo nor Brazil need to travel to where the car is to work on it. Instead, each has a partially finished car in their back yard. If Tokyo finishes constructing the radiator, she can submit that work to their sentient AI named Gitty. Upon receiving the work, Gitty stores the new state of the car based on the changes made. Then, before Brazil goes to start working on his copy of the car, he asks Gitty to update his car based on Gitty's data. That way the radiator Tokyo finished shows up on Brazil's car before he starts working.

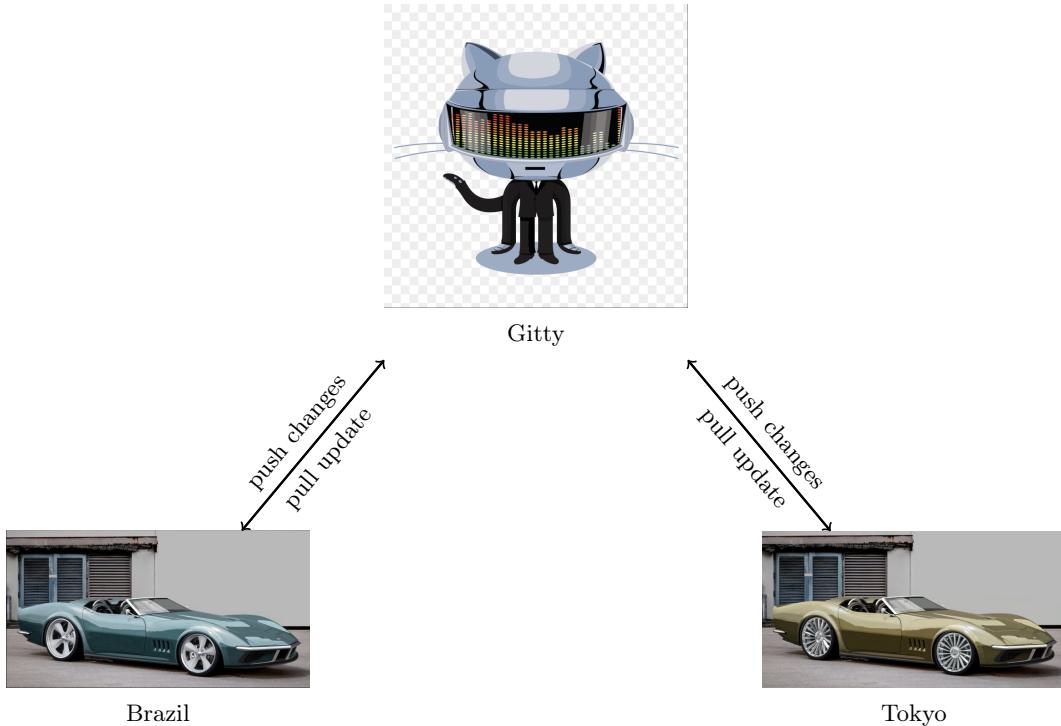

Figure 1.1: Data flow between cars via Gitty

That way, both Brazil and Tokyo can build the car locally without duplicating any of the work done by their counterpart. GitHub is the sentient AI Gitty in this example. Many coding projects are large and complicated with hundreds of contributors so its important to have something that can allow them to work efficiently with each other.

In our analogy, Tokyo or Brazil would submit their changes to Gitty. In Git, we call this ‘pushing’. Coders push their code to Git which records the changes. If another worker wants to update their code they then ‘pull’ from Git to get those changes. Projects are divided into ‘Repositories’ that exist online on a site called GitHub. Repositories house all the code a company is using for a specific purpose.

Git has a lot of complexities that you will no doubt encounter in your education and future work, but for now we will focus on learning how to push and pull and resolve any conflicts that might arise from that.

1.2 Navigation

We will be using the terminal to interact with GitHub so there are several commands you will need to be familiar with. The table below includes those we will use in this tutorial.

Table 1.1: Useful terminal and git commands

Command	Description
<code>cd <directory></code>	Change directory to <directory> (type ‘..’ to go back one directory)
<code>ls</code>	List all files/folders in the current directory
<code>pwd</code>	Print the current working directory
<code>git pull origin main</code>	updates your repository with what GitHub contains
<code>git add <file></code>	stages a changed/created file so that’s it’s ready to be pushed
<code>git commit -m "<message>"</code>	places a label on all staged changes
<code>git push origin main</code>	pushing staged and committed files to GitHub
<code>git status</code>	see details on what changes you’ve made that you haven’t pushed

To start, we need to navigate to our `GitHubIntro/` repository on our computer. Once you’ve opened a terminal, if it isn’t obvious what directory you are in you can use the `pwd` command to print your current directory.

```
~$ pwd
/home/username
```

Use the command `ls` to list the contents of your current directory.

```
~$ ls
Desktop      Downloads      Public      Videos
Documents    Pictures
```

Use the command `cd` to change your current directory. For example, if I wanted to navigate into the `Documents` folder, I would use the following command:

```
~$ cd Documents          # Change to the Documents folder
~$ pwd                  # Check that the current directory changed
/home/username/Documents
```

If you wish to go back a directory, use `cd` followed by a space and two periods “..”

```
~$ cd ..
~$ pwd
/home/username
```

Using these commands, navigate to the `GitHubIntro` folder inside your Volume 1 directory. Once you’re there, use `pwd` to check that you’re in the right folder. It should look like the following example only the ‘...’ will be replaced with your computer’s specific file path.

```
~$ pwd
/home/username/.../GitHubIntro
```

Now that we are inside the `GitHubIntro` folder (which is inside your Volume 1 repository) we can learn how to push and pull changes.

1.3 Push and Pull

Before starting to work on any repository based project, it’s good practice to pull from GitHub to make sure that the code that you have is up to date. This will avoid any conflicts in the updating process, which we will address later in the lab. In order to pull from the GitHub repository, use the command `git pull`

```
# Pull changes from your online repository to your local machine
~$ git pull origin main
```

After some terminal nonsense the changes should’ve been pulled onto your local machine.

Now let’s suppose we’ve changed an existing file or added files to our local copy. We need to update the remote (online) repository so it reflects these changes. In order to accomplish this we will use a series of commands: `git status`, `git add`, `git commit`, and `git push`.

`git status` shows us the current state of our repository. It should look something like what is shown in Figure 1.2:

Here, there are two sections: ‘Untracked files’ and ‘Changes not staged for commit’.

Untracked files are new files that do not yet exist on the remote repository. Files under the heading ‘Changes not staged for commit’ are files that already exist on the remote repository but are different than those on your local machine.

In the example above we see that three .png files have been added and one .tex file has been modified. We could stage all of these files (get them ready to be pushed) by using the command `git add --all`, however, sometimes we don’t want files to be pushed to GitHub (like if one is a data file that is too large to upload as you will experience in some of your ACME labs). Thus we will use `git add` followed by which files we specifically want to stage in order to have more control.

We can add each file with a separate `git add <the_file>` command or all at once with different files separated by spaces (i.e `git add <file1> <file2> ...`). Therefore the command to add the four files shown previously will be

```
git add car1.png car2.png robot.png GitHubIntro.tex
```

Figure 1.2: Terminal output after calling git status

```
rental@rentals-MBP GitHubIntro % git status
On branch GitHubIntro
Changes not staged for commit:
  (use "git add <file>..." to update what will be committed)
  (use "git restore <file>..." to discard changes in working directory)
    modified:   GitHubIntro.tex

Untracked files:
  (use "git add <file>..." to include in what will be committed)
    car1.png
    car2.png
    robot.png

no changes added to commit (use "git add" and/or "git commit -a")
rental@rentals-MBP GitHubIntro %
```

```
[rental@rentals-MBP GitHubIntro % git status
On branch GitHubIntro
Changes to be committed:
  (use "git restore --staged <file>..." to unstage)
    modified:   GitHubIntro.tex
    new file:   car1.png
    new file:   car2.png
    new file:   robot.png

rental@rentals-MBP GitHubIntro %
```

After that command we can use `git status` again to check what has been staged (see Figure ??)

Now all staged changes are shown in green under ‘Changes to be committed’. If there were files that we didn’t `git add` they would still be highlighted in red.

Now that we have added the changes we need to actual commit them. We can think of the difference between adding and committing in terms packing up a box. Using `git add` is like putting something in the box but using `git commit` is like taping the box shut and putting a label on it. Then, when we push, we are sending that box to the online github repository where the label of the box will be recorded in case the contents of that particular box is needed in the future.

Coding can be a fickle thing so it is often useful to look at or go back to previous versions of a code base. For this reason it is important that the label on our box be descriptive so that we can easily identify what is in the box if we want come back to it later. The commit command to use is as follows:

```
git commit -m "my very descriptive commit message"
```

Here the ‘-m’ means messsage and allows us to specify the label of our box in the quotations that follow it.

One thing to notee is that once changes have been committed, they will no longer appear in the `git status` output.

Now all there is left to do is send the box on its way by using `git push`. The syntax of this command is as follows:

```
git push origin <branch name>
```

A branch is just another copy of the repository. They are usually used on large projects to avoid merge conflicts and make development more organized. The default branch created in a repository is called ‘main’. We will not need branches in the ACME coursework so the push command will always be

```
git push origin main
```

Problem 1. In `github_intro.py` make `problem1` return a string with your first and last name. Then use the information above to add, commit, and push the change to GitHub. Go to GitHub, find the file you pushed to, and make sure the changes are reflected there.

Hint: Take note of how you found `github_intro.py` on GitHub since that’ll be important in problem 2.

This completes the walkthrough of pulling and pushing changes. Now we approach the topic of what happens when your local copy and the online copy conflict.

1.4 Merge Conflicts

We mentioned in the previous section that it’s good practice to pull changes from GitHub before making any of your own changes. This ensures that your code is completely up to date before doing any work. However, no one remembers to pull first every time. Making changes before pulling can create discrepancies between what exists on your local machine and what exists online. When this happens it is called a merge conflict.

Since git tracks changed files, it will not let you push changes you’ve made if there are changes on the remote that you haven’t pulled yet. If you attempt to push without realizing that you haven’t pulled, you may get a terminal message that looks like this:

Git does not want to override any changes made on either end so when a merge conflict occurs it notifies you. There are two kinds of merge conflicts, those that can be auto-resolved by Git, and those that need to be manually resolved

Figure 1.3: Message indicating a need to pull before pushing.

```
④ rental@rentals-MBP GitHubIntro % git push origin test_branch
To github.com:jrhmc1/Jupiter-Resonances.git
 ! [rejected]      test_branch -> test_branch (fetch first)
error: failed to push some refs to 'github.com:jrhmc1/Jupiter-Resonances.git'
hint: Updates were rejected because the remote contains work that you do
hint: not have locally. This is usually caused by another repository pushing
hint: to the same ref. You may want to first integrate the remote changes
hint: (e.g., 'git pull ...') before pushing again.
hint: See the 'Note about fast-forwards' in 'git push --help' for details.
○ rental@rentals-MBP GitHubIntro %
```

1.4.1 Auto-resolvable conflicts

This kind of conflict occurs when remote and local changes to a single file occur on **different lines**. In this case, Git can auto-resolve the conflict by accepting the local changes online and depositing the online changes locally.

For example, let's say your friend Peter changed the name of a function on line 12 and you added a return statement on line 37 of the same file. Git would still notify you of a merge conflict but can auto-resolve the conflict by putting the new name of the function on line 12 in your local machine and recording your return statement on the online version.

Even though Git can auto-resolve the conflict, it still gives you the option to provide the auto-resolve commit with a label (message) since Git is effectively creating a new commit. When this happens, your terminal window will look something like Figure 1.4.

Figure 1.4: Terminal window indicating an auto-resolvable merge conflict

```
Merge branch 'test_branch' of github.com:jrhmc1/Jupiter-Resonances into test_branch
# Please enter a commit message to explain why this merge is necessary,
# especially if it merges an updated upstream into a topic branch.
#
# Lines starting with '#' will be ignored, and an empty message aborts
# the commit.
~
```

ACHTUNG!

This window is actually a file that's opened in your terminal with the vim text editor. Vim is notorious for being difficult to use because of its gamut of eccentric commands. Rather than include a crash course on vim here, we will simply show you how to exit this window. Git will finish the auto-merge using a default commit message when the file is closed.

To exit a file opened in vim simply type :q. the ':' tells vim to execute the next typed command and the 'q' directs the text editor to quit. Once the vim window has closed git should auto-merge the changes. You may need to add and commit again to finish pushing.

NOTE

Git has several ways it can try to automatically merge a file. When you first get a merge conflict, you may see a window similar to the one shown below prompting you to tell Git which way to use when auto-merging.

```
hint: You have divergent branches and need to specify how to reconcile them.
hint: You can do so by running one of the following commands sometime before
hint: your next pull:
hint:
hint:   git config pull.rebase false  # merge
hint:   git config pull.rebase true   # rebase
hint:   git config pull.ff only     # fast-forward only
hint:
hint: You can replace "git config" with "git config --global" to set a default
hint: preference for all repositories. You can also pass --rebase, --no-rebase,
hint: or --ff-only on the command line to override the configured default per
hint: invocation.
fatal: Need to specify how to reconcile divergent branches.
```

In this case, choosing any of the three listed commands is valid. However, `git config pull.rebase false` will retain the most commit information and is therefore recommended.

Simply type that command in the terminal and then try pulling again to resolve this issue.

1.4.2 Manually-resolvable conflict

If a local and remote change occur on the same line of a modified file, git cannot automatically resolve it and will give a message in the terminal that looks like Figure 1.5

On the line that begins with 'CONFLICT' git will show you which files have a merge conflict. In most IDEs (such as VS Code) opening a file that has a merge conflict will allow you to click a button to decide which change you want to keep. The code in conflict will be surrounded by some '<' and '>' characters and will have which change is local and which is incoming labeled. It should look like Figure 1.6.

Once you've decided which change you want to keep you can simply click 'Accept current change' or 'Accept incoming change' and your IDE will place only that code in the document. If there are multiple conflicts, repeat this for each one. Once that has been completed, you may need to add, and commit the merged file again, then you can finish pushing your changes to github.

Figure 1.5: Terminal information to explain the failure of an auto-merge.

```
⑤ rental@rentals-MBP GitHubIntro % git pull origin test_branch
remote: Enumerating objects: 9, done.
remote: Counting objects: 100% (9/9), done.
remote: Compressing objects: 100% (5/5), done.
remote: Total 5 (delta 4), reused 0 (delta 0), pack-reused 0
Unpacking objects: 100% (5/5), 1.08 KiB | 110.00 KiB/s, done.
From github.com:jrhmc1/Jupiter-Resonances
 * branch            test_branch    -> FETCH_HEAD
   a51e8f63..96d2b630  test_branch    -> origin/test_branch
Auto-merging Volume1/GitHubIntro/github_intro.py
CONFLICT (content): Merge conflict in Volume1/GitHubIntro/github_intro.py
Automatic merge failed; fix conflicts and then commit the result.
⑥ rental@rentals-MBP GitHubIntro %
```

Figure 1.6: What manual merge conflict resolution looks like in an IDE.

```
12  def problem2():
13      """practice making a merge conflict with yourself by returning
14      different strings in different places.
15      """
16      Accept Current Change | Accept Incoming Change | Accept Both Changes | Compare Changes
17      <<<<< HEAD (Current Change)
18      | return "Dill Pickles"
19      =====
20      | return "Sweet Pickles"
21      >>>>> ec3ea180def265f71c14866d172714e7223b1401 (Incoming Change)
22
```

NOTE

You can also resolve manual merge conflicts in the terminal by using the `git checkout --ours` or the `git checkout --theirs` commands (`ours` to keep the local change, `theirs` to keep the incoming change), or by simply deleting everything you don't want. You'll still need to add, commit, and push after the resolution.

Now that we've learned about merge conflicts, we will manually create one to see how they work. Normal merge conflicts are caused by two separate people pushing from two separate local machines. In order to create one by ourselves we'll need to make and commit a local change AND edit the file directly on GitHub, which will simulate a pushed change from a different source.

Problem 2. Make two sets of changes in problem 2.

1. The first should be auto-resolvable, so the local and remote changes to problem2 should be on two different lines. (**Hint:** Making a comment on one line on your local machine and a comment on a different line on github is an easy way to accomplish this.) Once both changes are committed, try pulling the changes onto your local machine and practice exiting from the vim window. Finish by pushing the merge resolution.
2. The second set of changes should cause a legitimate merge conflict that you'll have to manually resolve. To accomplish this, locally replace the 'raise' statement in problem 2 with a return statement that returns any string of your choice. Then replace the 'raise' statement on GitHub with a different string so they'll conflict. Commit both changes and pull, then use VS code or terminal commands to resolve the conflict. Finish by pushing the merge resolution

1.5 Pushing and Pulling directly from VS Code

Using terminal commands is not the only way to use Git. Many IDE's have pushing and pulling user interfaces built into them. While terminal commands lend a measure of control and are more useful for more complicated Git functionality, using an IDE's Git tools can streamline and simplify the process. Since we've recommended the installation and usage of VS Code as a general IDE, we'll show how to use the git functionality on VS Code specifically. Other IDE's Git tools should be fairly similar.

1.5.1 Where to look

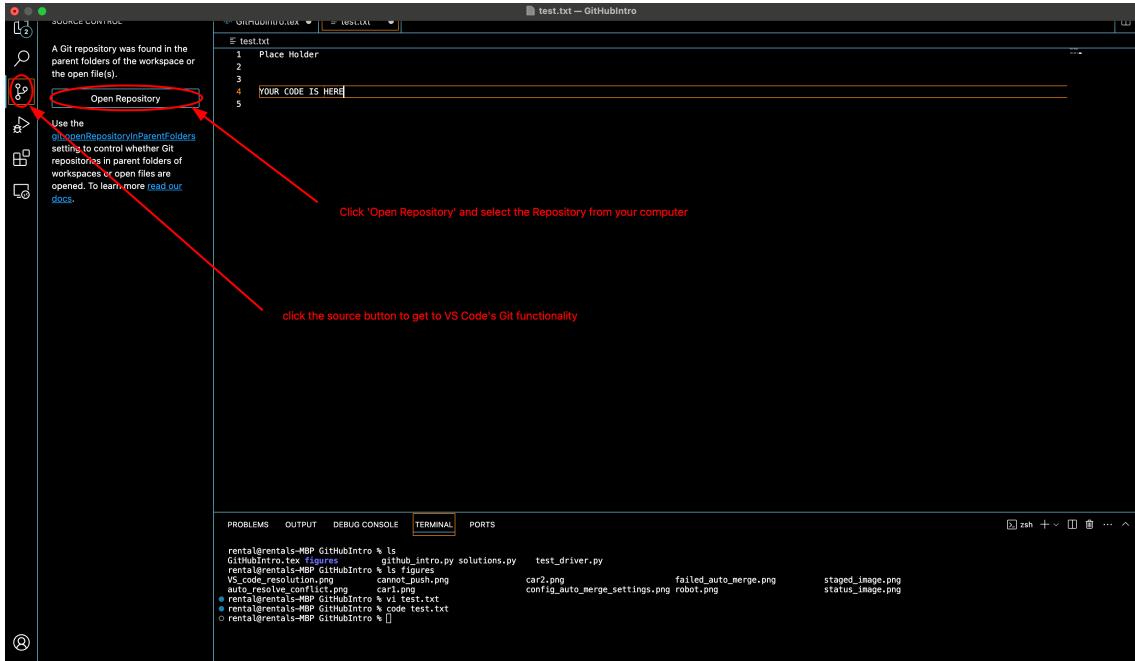

To access VS Code's Git tools you must first open your repository in VS Code. This is done by selecting the 'Source' tab on the left side, selecting 'Open Repository', and then searching for the repository you're working with on your computer. Figure 1.7 shows how this might look in a VS Code window.

After that, the Git tools should be visible. In Figure 1.8, the locations of where to find the commands discussed previously are shown. The descriptions of those locations follow:

1. Files under 'Changes' are files that need to be committed. The 'U' means its a new file and the 'M' means its an old file that's been modified. Clicking the '+' button is equivalent to `git add <that file>`. Clicking it will also move the file from the 'Changes' section to the 'Staged Changes' section
2. This will commit any files that have been added with the plus sign from item 1.
3. This is where you will write the commit message that would normally go in the quotations after `git commit -m`.
4. Here is where you will find the options to push and pull as well as many other Git actions

In VS Code. Merge conflicts will be handled similarly to when we were working in the terminal, except messages will appear in popups rather than in terminal output. Conflicts that need to be manually resolved can still be resolved by using the buttons in the open file in VS Code. Additionally, completing your push after the conflict resolution will still be necessary.

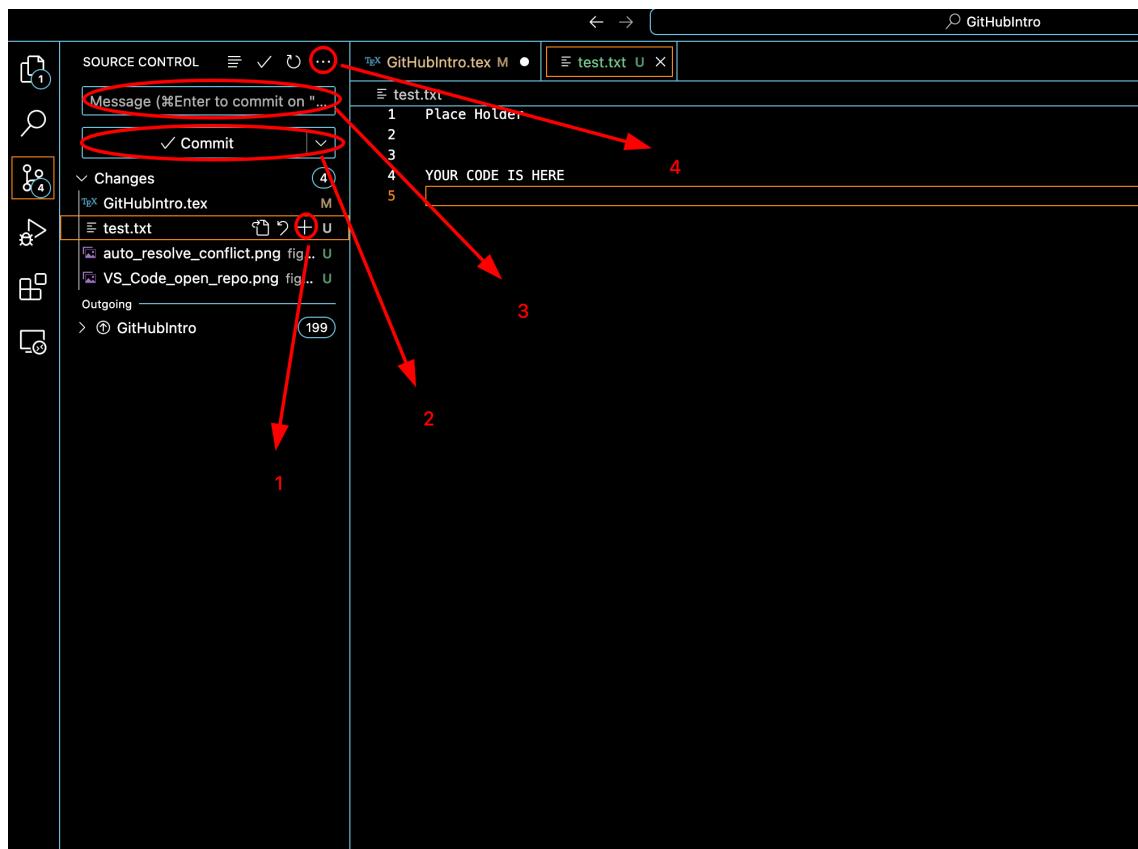

Figure 1.7: Where to go to open your Repo in VS Code.

1.6 Conclusion

This completes our preliminary tutorial of Git. Git has many more useful functions but for the purpose of completing your ACME labs, pushing, pulling, and resolving conflicts is enough to get started. However, Git skills are incredibly useful in industry and developing them further on your own can only benefit you.

Figure 1.8: Main buttons to us VS Code's Git tools

2

Linear Transformations

Lab Objective: *Linear transformations are the most basic and essential operators in vector space theory. In this lab we visually explore how linear transformations alter points in the Cartesian plane. We also empirically explore the computational cost of applying linear transformations via matrix multiplication.*

Linear Transformations

A *linear transformation* is a mapping between vector spaces that preserves addition and scalar multiplication. More precisely, let V and W be vector spaces over a common field \mathbb{F} . A map $L : V \rightarrow W$ is a linear transformation from V into W if

$$L(a\mathbf{x}_1 + b\mathbf{x}_2) = aL\mathbf{x}_1 + bL\mathbf{x}_2$$

for all vectors $\mathbf{x}_1, \mathbf{x}_2 \in V$ and scalars $a, b \in \mathbb{F}$.

Every linear transformation L from an m -dimensional vector space into an n -dimensional vector space can be represented by an $m \times n$ matrix A , called the *matrix representation* of L . To apply L to a vector \mathbf{x} , left multiply by its matrix representation. This results in a new vector \mathbf{x}' , where each component is some linear combination of the elements of \mathbf{x} . For linear transformations from \mathbb{R}^2 to \mathbb{R}^2 , this process has the form

$$A\mathbf{x} = \begin{bmatrix} a & b \\ c & d \end{bmatrix} \begin{bmatrix} x \\ y \end{bmatrix} = \begin{bmatrix} ax + by \\ cx + dy \end{bmatrix} = \begin{bmatrix} x' \\ y' \end{bmatrix} = \mathbf{x}'.$$

Linear transformations can be interpreted geometrically. To demonstrate this, consider the array of points H that collectively form a picture of a horse, stored in the file `horse.npy`. The coordinate pairs \mathbf{x}_i are organized by column, so the array has two rows: one for x -coordinates, and one for y -coordinates. Matrix multiplication on the left transforms each coordinate pair, resulting in another matrix H' whose columns are the transformed coordinate pairs:

$$\begin{aligned} AH = A \begin{bmatrix} x_1 & x_2 & x_3 & \dots \\ y_1 & y_2 & y_3 & \dots \end{bmatrix} &= A \begin{bmatrix} \mathbf{x}_1 & \mathbf{x}_2 & \mathbf{x}_3 & \dots \end{bmatrix} = \begin{bmatrix} A\mathbf{x}_1 & A\mathbf{x}_2 & A\mathbf{x}_3 & \dots \end{bmatrix} \\ &= \begin{bmatrix} \mathbf{x}'_1 & \mathbf{x}'_2 & \mathbf{x}'_3 & \dots \end{bmatrix} = \begin{bmatrix} x'_1 & x'_2 & x'_3 & \dots \\ y'_1 & y'_2 & y'_3 & \dots \end{bmatrix} = H'. \end{aligned}$$

To begin, use `np.load()` to extract the array from the `npy` file, then plot the unaltered points as individual pixels. See Figure 2.1 for the result.

```
>>> import numpy as np
>>> from matplotlib import pyplot as plt

# Load the array from the .npy file.
>>> data = np.load("horse.npy")

# Plot the x row against the y row with black pixels.
>>> plt.plot(data[0], data[1], 'k,')

# Set the window limits to [-1, 1] by [-1, 1] and make the window square.
>>> plt.axis([-1, 1, -1, 1])
>>> plt.gca().set_aspect("equal")
>>> plt.show()
```

Types of Linear Transformations

Linear transformations from \mathbb{R}^2 into \mathbb{R}^2 can be classified in a few ways.

- **Stretch:** Stretches or compresses the vector along each axis. The matrix representation is diagonal:

$$\begin{bmatrix} a & 0 \\ 0 & b \end{bmatrix}.$$

If $a = b$, the transformation is called a *dilation*. The stretch in Figure 2.1 uses $a = \frac{1}{2}$ and $b = \frac{6}{5}$ to compress the x -axis and stretch the y -axis.

- **Shear:** Slants the vector by a scalar factor horizontally or vertically (or both simultaneously). The matrix representation is

$$\begin{bmatrix} 1 & a \\ b & 1 \end{bmatrix}.$$

Pure horizontal shears ($b = 0$) skew the x -coordinate of the vector while pure vertical shears ($a = 0$) skew the y -coordinate. Figure 2.1 has a horizontal shear with $a = \frac{1}{2}, b = 0$.

- **Reflection:** Reflects the vector about a line that passes through the origin. The reflection about the line spanned by the vector $[a, b]^T$ has the matrix representation

$$\frac{1}{a^2 + b^2} \begin{bmatrix} a^2 - b^2 & 2ab \\ 2ab & b^2 - a^2 \end{bmatrix}.$$

The reflection in Figure 2.1 reflects the image about the y -axis ($a = 0, b = 1$).

- **Rotation:** Rotates the vector around the origin. A counterclockwise rotation of θ radians has the following matrix representation:

$$\begin{bmatrix} \cos \theta & -\sin \theta \\ \sin \theta & \cos \theta \end{bmatrix}$$

A negative value of θ performs a clockwise rotation. Choosing $\theta = \frac{\pi}{2}$ produces the rotation in Figure 2.1.

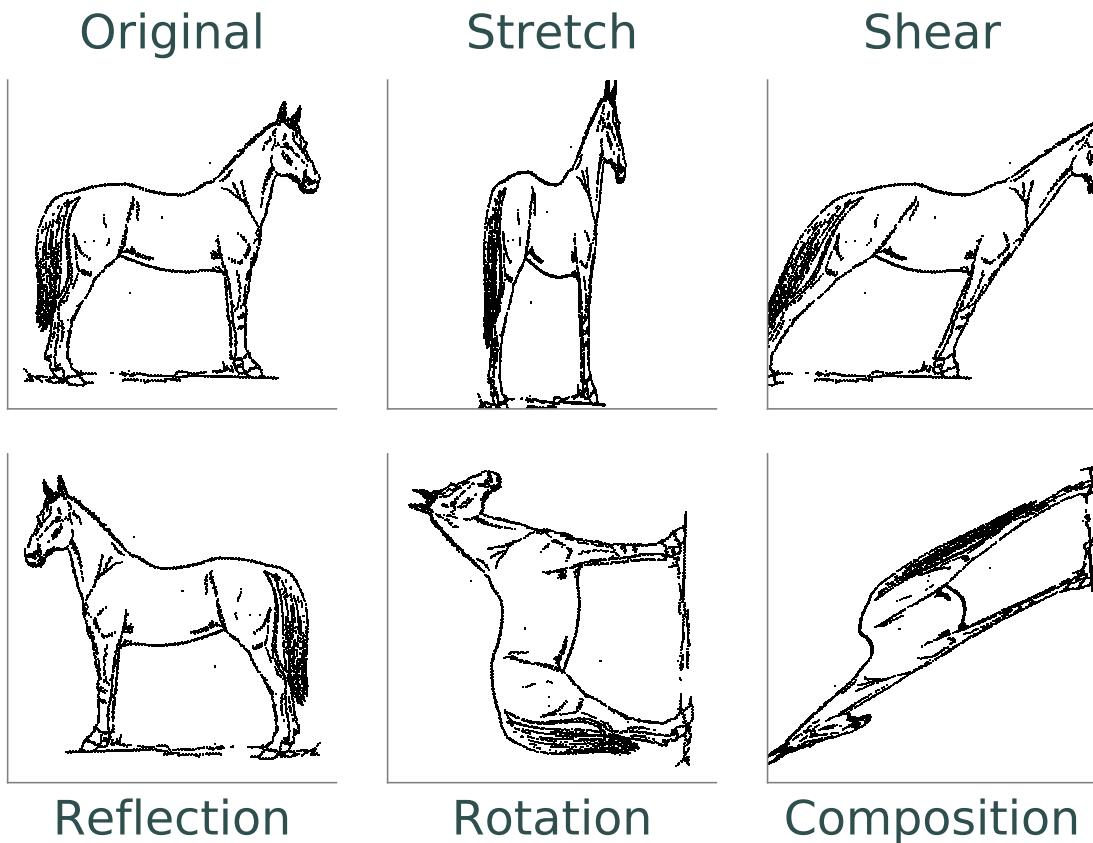

Figure 2.1: The points stored in `horse.npy` under various linear transformations.

Problem 1. Write a function for each type of linear transformation. Each function should accept an array to transform and the scalars that define the transformation (a and b for stretch, shear, and reflection, and θ for rotation). Construct the matrix representation, left multiply it with the input array, and return a transformation of the data.

To test these functions, write a function to plot the original points in `horse.npy` together with the transformed points in subplots for a side-by-side comparison. Compare your results to Figure 2.1.

Compositions of Linear Transformations

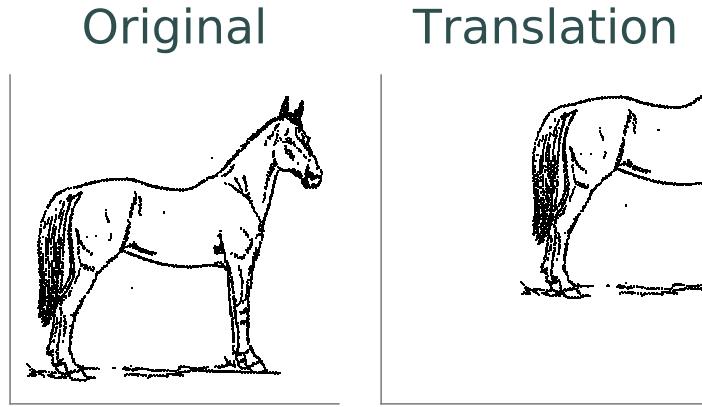

Let V , W , and Z be finite-dimensional vector spaces. If $L : V \rightarrow W$ and $K : W \rightarrow Z$ are linear transformations with matrix representations A and B , respectively, then the *composition* function $KL : V \rightarrow Z$ is also a linear transformation, and its matrix representation is the matrix product BA .

For example, if S is a matrix representing a shear and R is a matrix representing a rotation, then RS represents a shear followed by a rotation. In fact, any linear transformation $L : \mathbb{R}^2 \rightarrow \mathbb{R}^2$ is a composition of the four transformations discussed above. Figure 2.1 displays the composition of all four previous transformations, applied in order (stretch, shear, reflection, then rotation).

Affine Transformations

All linear transformations map the origin to itself. An *affine transformation* is a mapping between vector spaces that preserves the relationships between points and lines, but that may not preserve the origin. Every affine transformation T can be represented by a matrix A and a vector \mathbf{b} . To apply T to a vector x , calculate $Ax + \mathbf{b}$. If $\mathbf{b} = \mathbf{0}$ then the transformation is linear, and if $A = I$ but $\mathbf{b} \neq \mathbf{0}$ then it is called a *translation*.

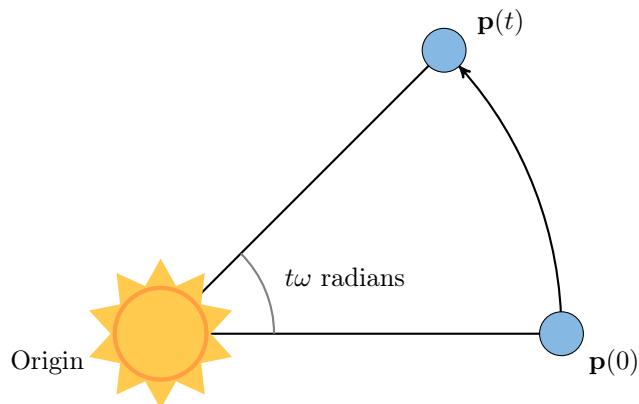

For example, if T is the translation with $\mathbf{b} = [\frac{3}{4}, \frac{1}{2}]^\top$, then applying T to an image will shift it right by $\frac{3}{4}$ and up by $\frac{1}{2}$. This translation is illustrated below.

Affine transformations include all compositions of stretches, shears, rotations, reflections, and translations. For example, if S represents a shear and R a rotation, and if \mathbf{b} is a vector, then $RS\mathbf{x} + \mathbf{b}$ shears, then rotates, then translates \mathbf{x} .

Modeling Motion with Affine Transformations

Affine transformations can be used to model particle motion, such as a planet rotating around the sun. Let the sun be the origin, the planet's location at time t be given by the vector $\mathbf{p}(t)$, and suppose the planet has angular velocity ω (a measure of how fast the planet goes around the sun). To find the planet's position at time t given the planet's initial position $\mathbf{p}(0)$, rotate the vector $\mathbf{p}(0)$ around the origin by $t\omega$ radians. Thus if $R(\theta)$ is the matrix representation of the linear transformation that rotates a vector around the origin by θ radians, then $\mathbf{p}(t) = R(t\omega)\mathbf{p}(0)$.

Composing the rotation with a translation shifts the center of rotation away from the origin, yielding more complicated motion.

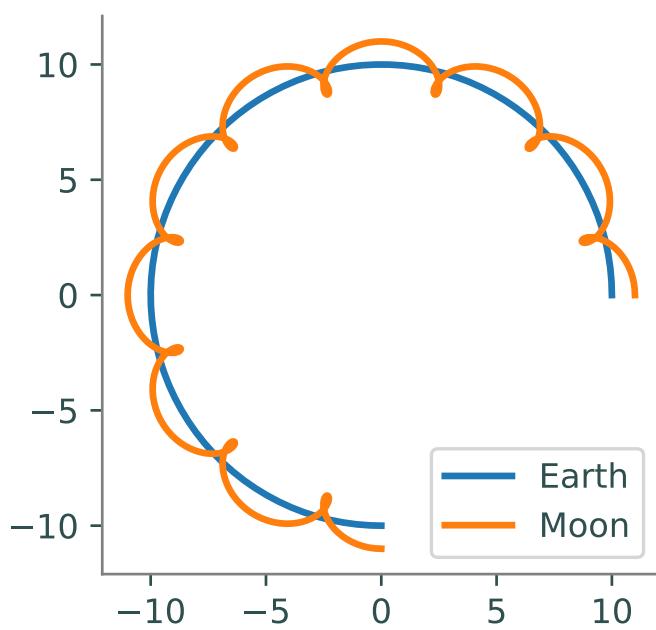

Problem 2. The moon orbits the earth while the earth orbits the sun. Assuming circular orbits, we can compute the trajectories of both the earth and the moon using only linear and affine transformations.

Assume an orientation where both the earth and moon travel counterclockwise, with the sun at the origin. Let $\mathbf{p}_e(t)$ and $\mathbf{p}_m(t)$ be the positions of the earth and the moon at time t , respectively, and let ω_e and ω_m be each celestial body's angular velocity. For a particular time t , we calculate $\mathbf{p}_e(t)$ and $\mathbf{p}_m(t)$ with the following steps.

1. Compute $\mathbf{p}_e(t)$ by rotating the initial vector $\mathbf{p}_e(0)$ counterclockwise about the origin by $t\omega_e$ radians.
2. Calculate the position of the moon relative to the earth at time t by rotating the vector $\mathbf{p}_m(0) - \mathbf{p}_e(0)$ counterclockwise about the origin by $t\omega_m$ radians.
3. To compute $\mathbf{p}_m(t)$, translate the vector resulting from the previous step by $\mathbf{p}_e(t)$.

Write a function that accepts a final time T , initial positions x_e and x_m , and the angular momenta ω_e and ω_m . Assuming initial positions $\mathbf{p}_e(0) = (x_e, 0)$ and $\mathbf{p}_m(0) = (x_m, 0)$, plot $\mathbf{p}_e(t)$ and $\mathbf{p}_m(t)$ over the time interval $t \in [0, T]$.

Setting $T = \frac{3\pi}{2}$, $x_e = 10$, $x_m = 11$, $\omega_e = 1$, and $\omega_m = 13$, your plot should resemble the following figure (fix the aspect ratio with `ax.set_aspect("equal")`). Note that a more celestially accurate figure would use $x_e = 400$, $x_m = 401$ (the interested reader should see <http://www.math.nus.edu.sg/aslaksen/teaching/convex.html>).

Timing Matrix Operations

Linear transformations are easy to perform via matrix multiplication. However, performing matrix multiplication with very large matrices can strain a machine's time and memory constraints. For the remainder of this lab we take an empirical approach in exploring how much time and memory different matrix operations require.

Timing Code

Recall that the `time` module's `time()` function measures the number of seconds since the Epoch. To measure how long it takes for code to run, record the time just before and just after the code in question, then subtract the first measurement from the second to get the number of seconds that have passed. Additionally, in IPython, the quick command `%timeit` uses the `timeit` module to quickly time a single line of code.

```
In [1]: import time

In [2]: def for_loop():
....:     """Go through ten million iterations of nothing."""
....:     for _ in range(int(1e7)):
....:         pass

In [3]: def time_for_loop():
....:     """Time for_loop() with time.time()."""
....:     start = time.time()           # Clock the starting time.
....:     for_loop()
....:     return time.time() - start   # Return the elapsed time.

In [4]: time_for_loop()
0.24458789825439453

In [5]: %timeit for_loop()
248 ms +- 5.35 ms per loop (mean +- std. dev. of 7 runs, 1 loop each)
```

Timing an Algorithm

Most algorithms have at least one input that dictates the size of the problem to be solved. For example, the following functions take in a single integer n and produce a random vector of length n as a list or a random $n \times n$ matrix as a list of lists.

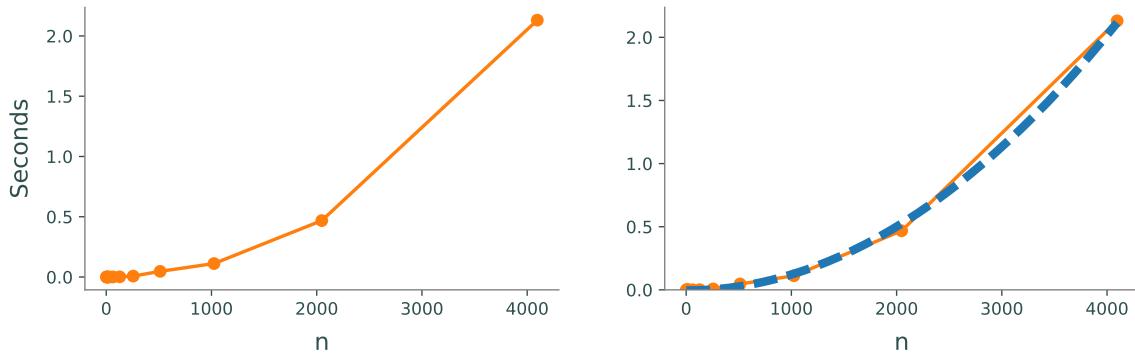

```
from random import random
def random_vector(n):          # Equivalent to np.random.random(n).tolist()
    """Generate a random vector of length n as a list."""
    return [random() for i in range(n)]

def random_matrix(n):          # Equivalent to np.random.random((n,n)).tolist()
    """Generate a random nxn matrix as a list of lists."""
    return [[random() for j in range(n)] for i in range(n)]
```

Executing `random_vector(n)` calls `random()` n times, so doubling n should about double the amount of time `random_vector(n)` takes to execute. By contrast, executing `random_matrix(n)` calls `random()` n^2 times (n times per row with n rows). Therefore doubling n will likely more than double the amount of time `random_matrix(n)` takes to execute, especially if n is large.

To visualize this phenomenon, we time `random_matrix()` for $n = 2^1, 2^2, \dots, 2^{12}$ and plot n against the execution time. The result is displayed below on the left.

```
>>> domain = 2**np.arange(1, 13)
>>> times = []
>>> for n in domain:
...     start = time.time()
...     random_matrix(n)
...     times.append(time.time() - start)
...
>>> plt.plot(domain, times, 'g.-', linewidth=2, markersize=15)
>>> plt.xlabel("n", fontsize=14)
>>> plt.ylabel("Seconds", fontsize=14)
>>> plt.show()
```

The figure on the left shows that the execution time for `random_matrix(n)` increases quadratically in n . In fact, the blue dotted line in the figure on the right is the parabola $y = an^2$, which fits nicely over the timed observations. Here a is a small constant, but it is much less significant than the exponent on the n . To represent this algorithm's growth, we ignore a altogether and write `random_matrix(n) $\sim n^2$` .

NOTE

An algorithm like `random_matrix(n)` whose execution time increases quadratically with n is called $O(n^2)$, denoted by `random_matrix(n) $\in O(n^2)$` . Big-oh notation is common for indicating both the *temporal complexity* of an algorithm (how the execution time grows with n) and the *spatial complexity* (how the memory usage grows with n).

Problem 3. Let A be an $m \times n$ matrix with entries a_{ij} , \mathbf{x} be an $n \times 1$ vector with entries x_k , and B be an $n \times p$ matrix with entries b_{ij} . The matrix-vector product $A\mathbf{x} = \mathbf{y}$ is a new $m \times 1$ vector and the matrix-matrix product $AB = C$ is a new $m \times p$ matrix. The entries y_i of \mathbf{y} and c_{ij} of C are determined by the following formulas:

$$y_i = \sum_{k=1}^n a_{ik}x_k \quad c_{ij} = \sum_{k=1}^n a_{ik}b_{kj}$$

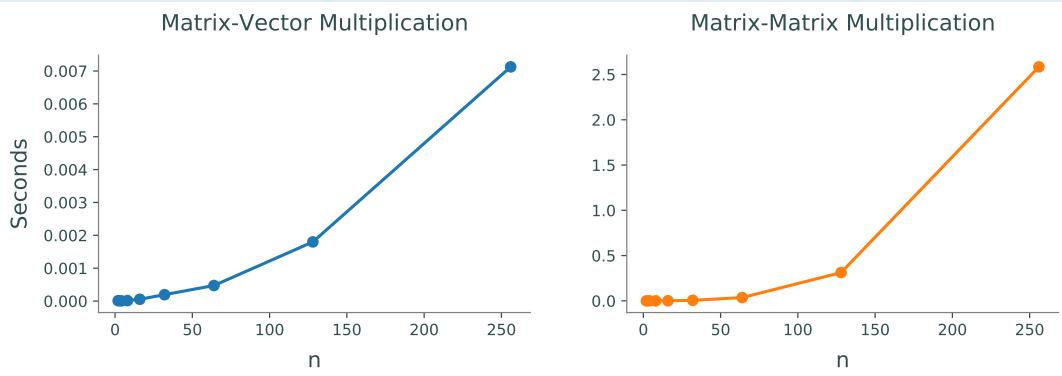

These formulas are implemented below **without** using NumPy arrays or operations.

```
def matrix_vector_product(A, x):      # Equivalent to np.dot(A,x).tolist()
    """Compute the matrix-vector product Ax as a list."""
    m, n = len(A), len(x)
    return [sum([A[i][k] * x[k] for k in range(n)]) for i in range(m)]

def matrix_matrix_product(A, B):        # Equivalent to np.dot(A,B).tolist()
    """Compute the matrix-matrix product AB as a list of lists."""
    m, n, p = len(A), len(B), len(B[0])
    return [[sum([A[i][k] * B[k][j] for k in range(n)])
            for j in range(p)]
            for i in range(m)]]
```

Time each of these functions with increasingly large inputs. Generate the inputs A , \mathbf{x} , and B with `random_matrix()` and `random_vector()` (so each input will be $n \times n$ or $n \times 1$). Only time the multiplication functions, not the generating functions.

Report your findings in a single figure with two subplots: one with matrix-vector times, and one with matrix-matrix times. Choose a domain for n so that your figure accurately describes the growth, but avoid values of n that lead to execution times of more than 1 minute. Your figure should resemble the following plots.

Logarithmic Plots

Though the two plots from Problem 3 look similar, the scales on the y -axes show that the actual execution times differ greatly. To be compared correctly, the results need to be viewed differently.

A *logarithmic plot* uses a logarithmic scale—with values that increase exponentially, such as $10^1, 10^2, 10^3, \dots$ —on one or both of its axes. The three kinds of log plots are listed below.

- **log-lin:** the x -axis uses a logarithmic scale but the y -axis uses a linear scale.
Use `plt.semilogx()` instead of `plt.plot()`.
- **lin-log:** the x -axis is uses a linear scale but the y -axis uses a log scale.
Use `plt.semilogy()` instead of `plt.plot()`.
- **log-log:** both the x and y -axis use a logarithmic scale.
Use `plt.loglog()` instead of `plt.plot()`.

Since the domain $n = 2^1, 2^2, \dots$ is a logarithmic scale and the execution times increase quadratically, we visualize the results of the previous problem with a log-log plot. The default base for the logarithmic scales on logarithmic plots in Matplotlib is 10. To change the base to 2 on each axis, specify the keyword arguments `base=2`.

Suppose the domain of n values are stored in `domain` and the corresponding execution times for `matrix_vector_product()` and `matrix_matrix_product()` are stored in `vector_times` and `matrix_times`, respectively. Then the following code produces the `left` subplot in Figure 2.5.

```
# Plot both curves on a base 2 log-log plot.
>>> plt.loglog(domain, vector_times, 'b.-', base=2, lw=2, label="Matrix-Vector")
>>> plt.loglog(domain, matrix_times, 'g.-', base=2, lw=2, label="Matrix-Matrix")

# Be sure to properly label your plots
>>> plt.title("log-log Plot")
>>> plt.xlabel('n')
>>> plt.ylabel("Seconds")
>>> plt.legend(loc="upper left")

>>> plt.show()
```

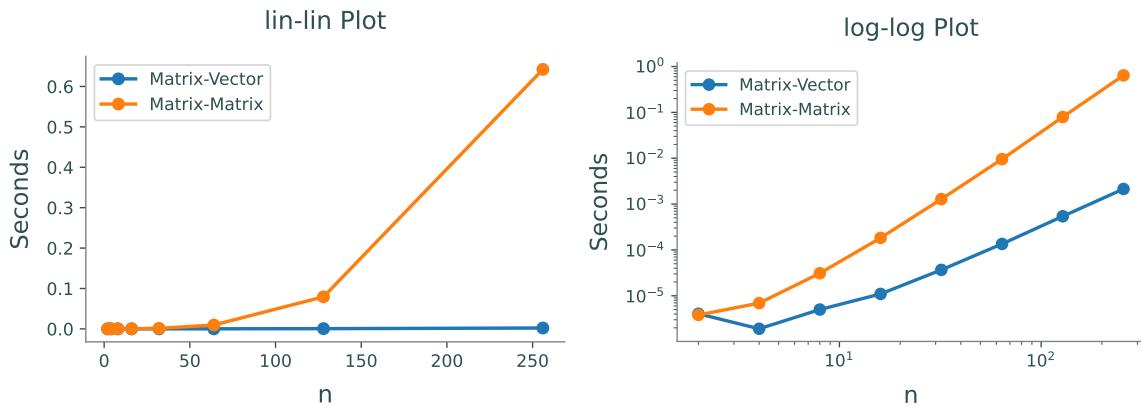

Figure 2.5

In the log-log plot, the slope of the `matrix_matrix_product()` line is about 3 and the slope of the `matrix_vector_product()` line is about 2. This reflects the fact that matrix-matrix multiplication (which uses 3 loops) is $O(n^3)$, while matrix-vector multiplication (which only has 2 loops) is only $O(n^2)$.

Problem 4. NumPy is built specifically for fast numerical computations. Repeat the experiment of Problem 3, timing the following operations:

- matrix-vector multiplication with `matrix_vector_product()`.
- matrix-matrix multiplication with `matrix_matrix_product()`.
- matrix-vector multiplication with `np.dot()` or `@`.
- matrix-matrix multiplication with `np.dot()` or `@`.

Create a single figure with two subplots: one with all four sets of execution times on a regular linear scale, and one with all four sets of execution times on a log-log scale. Your results should resemble Figure 2.5 except it should have four lines on each subplot. Remember that `np.dot()` and `@` only work on NumPy arrays.

NOTE

Problem 4 shows that **matrix operations are significantly faster in NumPy than in plain Python**. Matrix-matrix multiplication grows cubically regardless of the implementation; however, with lists the times grows at a rate of an^3 while with NumPy the times grow at a rate of bn^3 , where a is much larger than b . NumPy is more efficient for several reasons:

1. Iterating through loops is very expensive. Many of NumPy's operations are implemented in C, which are much faster than Python loops.
2. Arrays are designed specifically for matrix operations, while Python lists are general purpose.
3. NumPy carefully takes advantage of computer hardware, efficiently using different levels of computer memory.

However, in Problem 4, the execution times for matrix multiplication with NumPy seem to increase somewhat inconsistently. This is because the fastest layer of computer memory can only handle so much information before the computer has to begin using a larger, slower layer of memory.

Additional Material

Image Transformation as a Class

Consider organizing the functions from Problem 1 into a class. The constructor might accept an array or the name of a file containing an array. This structure would make it easy to do several linear or affine transformations in sequence.

```
>>> horse = ImageTransformer("horse.npy")
>>> horse.stretch(.5, 1.2)
>>> horse.shear(.5, 0)
>>> horse.select(0, 1)
>>> horse.rotate(np.pi/2.)
>>> horse.translate(.75, .5)
>>> horse.display()
```

Animating Function Parameters

The plot in Problem 2 fails to fully convey the system's evolution over time because time itself is not part of the plot. The following function creates an animation for the earth and moon trajectories.

```
from matplotlib.animation import FuncAnimation

def solar_system_animation(earth, moon):
    """Animate the moon orbiting the earth and the earth orbiting the sun.

    Parameters:
        earth ((2,N) ndarray): The earth's position with x-coordinates on the
            first row and y coordinates on the second row.
        moon ((2,N) ndarray): The moon's position with x-coordinates on the
            first row and y coordinates on the second row.
    """
    fig, ax = plt.subplots(1, 1)                      # Make a figure explicitly←
    plt.axis([-15, 15, -15, 15])                     # Set the window limits.
    ax.set_aspect("equal")                            # Make the window square.
    earth_dot, = ax.plot([], [], 'C0o', ms=10)       # Blue dot for the earth.
    earth_path, = ax.plot([], [], 'C0-')              # Blue line for the earth.
    moon_dot, = ax.plot([], [], 'C2o', ms=5)         # Green dot for the moon.
    moon_path, = ax.plot([], [], 'C2-')              # Green line for the moon.
    ax.plot([0], [0], 'y*', ms=20)                   # Yellow star for the sun←

    def animate(index):
        earth_dot.set_data(earth[0, index], earth[1, index])
        earth_path.set_data(earth[0, :index], earth[1, :index])
        moon_dot.set_data(moon[0, index], moon[1, index])
        moon_path.set_data(moon[0, :index], moon[1, :index])
        return earth_dot, earth_path, moon_dot, moon_path,
    a = FuncAnimation(fig, animate, frames=earth.shape[1], interval=25)
```

```
plt.show()
```

3

Linear Systems

Lab Objective: *The fundamental problem of linear algebra is solving the linear system $A\mathbf{x} = \mathbf{b}$, given that a solution exists. There are many approaches to solving this problem, each with different pros and cons. In this lab we implement the LU decomposition and use it to solve square linear systems. We also introduce SciPy, together with its libraries for linear algebra and working with sparse matrices.*

Gaussian Elimination

The standard approach for solving the linear system $A\mathbf{x} = \mathbf{b}$ on paper is reducing the augmented matrix $[A | \mathbf{b}]$ to row-echelon form (REF) via *Gaussian elimination*, then using back substitution. The matrix is in REF when the leading non-zero term in each row is the diagonal term, so the matrix is upper triangular.

At each step of Gaussian elimination, there are three possible operations: swapping two rows, multiplying one row by a scalar value, or adding a scalar multiple of one row to another. Many systems, like the one displayed below, can be reduced to REF using only the third type of operation. First, use multiples of the first row to get zeros below the diagonal in the first column, then use a multiple of the second row to get zeros below the diagonal in the second column.

$$\left[\begin{array}{ccc|c} 1 & 1 & 1 & 1 \\ 1 & 4 & 2 & 3 \\ 4 & 7 & 8 & 9 \end{array} \right] \rightarrow \left[\begin{array}{ccc|c} 1 & 1 & 1 & 1 \\ 0 & 3 & 1 & 2 \\ 4 & 7 & 8 & 9 \end{array} \right] \rightarrow \left[\begin{array}{ccc|c} 1 & 1 & 1 & 1 \\ 0 & 3 & 1 & 2 \\ 0 & 3 & 4 & 5 \end{array} \right] \rightarrow \left[\begin{array}{ccc|c} 1 & 1 & 1 & 1 \\ 0 & 3 & 1 & 2 \\ 0 & 0 & 3 & 3 \end{array} \right]$$

Each of these operations is equivalent to left-multiplying by a *type III elementary matrix*, the identity with a single non-zero non-diagonal term. If row operation k corresponds to matrix E_k , the following equation is $E_3E_2E_1A = U$.

$$\left[\begin{array}{ccc} 1 & 0 & 0 \\ 0 & 1 & 0 \\ 0 & -1 & 1 \end{array} \right] \left[\begin{array}{ccc} 1 & 0 & 0 \\ 0 & 1 & 0 \\ -4 & 0 & 1 \end{array} \right] \left[\begin{array}{ccc} 1 & 0 & 0 \\ -1 & 1 & 0 \\ 0 & 0 & 1 \end{array} \right] \left[\begin{array}{ccc|c} 1 & 1 & 1 & 1 \\ 1 & 4 & 2 & 3 \\ 4 & 7 & 8 & 9 \end{array} \right] = \left[\begin{array}{ccc|c} 1 & 1 & 1 & 1 \\ 0 & 3 & 1 & 2 \\ 0 & 0 & 3 & 3 \end{array} \right]$$

However, matrix multiplication is an inefficient way to implement row reduction. Instead, modify the matrix in place (without making a copy), changing only those entries that are affected by each row operation.

```
>>> import numpy as np

>>> A = np.array([[1, 1, 1, 1],
...                 [1, 4, 2, 3],
...                 [4, 7, 8, 9]], dtype=np.float)

# Reduce the 0th column to zeros below the diagonal.
>>> A[1, 0:] -= (A[1, 0] / A[0, 0]) * A[0]
>>> A[2, 0:] -= (A[2, 0] / A[0, 0]) * A[0]

# Reduce the 1st column to zeros below the diagonal.
>>> A[2, 1:] -= (A[2, 1] / A[1, 1]) * A[1, 1:]
>>> print(A)
[[ 1.  1.  1.  1.]
 [ 0.  3.  1.  2.]
 [ 0.  0.  3.  3.]]
```

Note that the final row operation modifies only part of the third row to avoid spending the computation time of adding 0 to 0.

If a 0 appears on the main diagonal during any part of row reduction, the approach given above tries to divide by 0. Swapping the current row with one below it that does not have a 0 in the same column solves this problem. This is equivalent to left-multiplying by a type II elementary matrix, also called a *permutation matrix*.

ACHTUNG!

Gaussian elimination is not always numerically stable. In other words, it is susceptible to rounding error that may result in an incorrect final matrix. Suppose that, due to roundoff error, the matrix A has a very small entry on the diagonal.

$$A = \begin{bmatrix} 10^{-15} & 1 \\ -1 & 0 \end{bmatrix}$$

Though 10^{-15} is essentially zero, instead of swapping the first and second rows to put A in REF, a computer might multiply the first row by 10^{15} and add it to the second row to eliminate the -1 . The resulting matrix is far from what it would be if the 10^{-15} were actually 0.

$$\begin{bmatrix} 10^{-15} & 1 \\ -1 & 0 \end{bmatrix} \rightarrow \begin{bmatrix} 10^{-15} & 1 \\ 0 & 10^{15} \end{bmatrix}$$

Round-off error can propagate through many steps in a calculation. The NumPy routines that employ row reduction use several tricks to minimize the impact of round-off error, but these tricks cannot fix every matrix.

Problem 1. Write a function that reduces an arbitrary square matrix A to REF. You may assume that A is invertible and that a 0 will never appear on the main diagonal (so only use type III row reductions, not type II). Avoid operating on entries that you know will be 0 before and after a row operation. Use at most two nested loops.

Test your function with small test cases that you can check by hand. Consider using `np.random.randint()` to generate a few manageable tests cases.

The LU Decomposition

The *LU decomposition* of a square matrix A is a factorization $A = LU$ where U is the **upper** triangular REF of A and L is the **lower** triangular product of the type III elementary matrices whose inverses reduce A to U . The LU decomposition of A exists when A can be reduced to REF using only type III elementary matrices (without any row swaps). However, the rows of A can always be permuted in a way such that the decomposition exists. If P is a permutation matrix encoding the appropriate row swaps, then the decomposition $PA = LU$ always exists.

Suppose A has an LU decomposition (not requiring row swaps). Then A can be reduced to REF with k row operations, corresponding to left-multiplying the type III elementary matrices E_1, \dots, E_k . Because there were no row swaps, each E_i is lower triangular, so each inverse E_i^{-1} is also lower triangular. Furthermore, since the product of lower triangular matrices is lower triangular, L is lower triangular:

$$\begin{aligned} E_k \dots E_2 E_1 A &= U \quad \longrightarrow \quad A = (E_k \dots E_2 E_1)^{-1} U \\ &= E_1^{-1} E_2^{-1} \dots E_k^{-1} U \\ &= LU. \end{aligned}$$

Thus, L can be computed by right-multiplying the identity by the matrices used to reduce U . However, in this special situation, each right-multiplication only changes one entry of L , matrix multiplication can be avoided altogether. The entire process, only slightly different than row reduction, is summarized below.

Algorithm 1

```

1: procedure LU DECOMPOSITION( $A$ )
2:    $m, n \leftarrow \text{shape}(A)$                                       $\triangleright$  Store the dimensions of  $A$ .
3:    $U \leftarrow \text{copy}(A)$                                       $\triangleright$  Make a copy of  $A$  with np.copy().
4:    $L \leftarrow I_m$                                           $\triangleright$  The  $m \times m$  identity matrix.
5:   for  $j = 0 \dots n - 1$  do
6:     for  $i = j + 1 \dots m - 1$  do
7:        $L_{i,j} \leftarrow U_{i,j} / U_{j,j}$ 
8:        $U_{i,j:} \leftarrow U_{i,j:} - L_{i,j} U_{j,j:}$ 
9:   return  $L, U$ 

```

Problem 2. Write a function that finds the LU decomposition of a square matrix. You may assume that the decomposition exists and requires no row swaps.

Forward and Backward Substitution

If $PA = LU$ and $A\mathbf{x} = \mathbf{b}$, then $L\mathbf{U}\mathbf{x} = PA\mathbf{x} = P\mathbf{b}$. This system can be solved by first solving $L\mathbf{y} = P\mathbf{b}$, then $\mathbf{U}\mathbf{x} = \mathbf{y}$. Since L and U are both triangular, these systems can be solved with backward and forward substitution. We can thus compute the LU factorization of A once, then use substitution to efficiently solve $A\mathbf{x} = \mathbf{b}$ for various values of \mathbf{b} .

Since the diagonal entries of L are all 1, the triangular system $L\mathbf{y} = \mathbf{b}$ has the form

$$\begin{bmatrix} 1 & 0 & 0 & \cdots & 0 \\ l_{21} & 1 & 0 & \cdots & 0 \\ l_{31} & l_{32} & 1 & \cdots & 0 \\ \vdots & \vdots & \vdots & \ddots & \vdots \\ l_{n1} & l_{n2} & l_{n3} & \cdots & 1 \end{bmatrix} \begin{bmatrix} y_1 \\ y_2 \\ y_3 \\ \vdots \\ y_n \end{bmatrix} = \begin{bmatrix} b_1 \\ b_2 \\ b_3 \\ \vdots \\ b_n \end{bmatrix}.$$

Matrix multiplication yields the equations

$$\begin{aligned} y_1 &= b_1, & y_1 &= b_1, \\ l_{21}y_1 + y_2 &= b_2, & y_2 &= b_2 - l_{21}y_1, \\ &\vdots &&\vdots \\ \sum_{j=1}^{k-1} l_{kj}y_j + y_k &= b_k, & y_k &= b_k - \sum_{j=1}^{k-1} l_{kj}y_j. \end{aligned} \tag{3.1}$$

The triangular system $U\mathbf{x} = \mathbf{y}$ yields similar equations, but in reverse order:

$$\begin{bmatrix} u_{11} & u_{12} & u_{13} & \cdots & u_{1n} \\ 0 & u_{22} & u_{23} & \cdots & u_{2n} \\ 0 & 0 & u_{33} & \cdots & u_{3n} \\ \vdots & \vdots & \vdots & \ddots & \vdots \\ 0 & 0 & 0 & \cdots & u_{nn} \end{bmatrix} \begin{bmatrix} x_1 \\ x_2 \\ x_3 \\ \vdots \\ x_n \end{bmatrix} = \begin{bmatrix} y_1 \\ y_2 \\ y_3 \\ \vdots \\ y_n \end{bmatrix},$$

$$\begin{aligned} u_{nn}x_n &= y_n, & x_n &= \frac{1}{u_{nn}}y_n, \\ u_{n-1,n-1}x_{n-1} + u_{n-1,n}x_n &= y_{n-1}, & x_{n-1} &= \frac{1}{u_{n-1,n-1}}(y_{n-1} - u_{n-1,n}x_n), \\ &\vdots &&\vdots \\ \sum_{j=k}^n u_{kj}x_j &= y_k, & x_k &= \frac{1}{u_{kk}} \left(y_k - \sum_{j=k+1}^n u_{kj}x_j \right). \end{aligned} \tag{3.2}$$

Problem 3. Write a function that, given A and \mathbf{b} , solves the square linear system $A\mathbf{x} = \mathbf{b}$. Use the function from Problem 2 to compute L and U , then use (3.1) and (3.2) to solve for \mathbf{y} , then \mathbf{x} . You may again assume that no row swaps are required ($P = I$ in this case).

UNIT TEST

Write a unit test for Problem 3, your solve function. It can be found in the `test_linear_systems.py` file and the unit test is named `test_solve`.

There are example unit tests for Problems 1 and 2 to help you structure your unit test.

SciPy

SciPy [JOP⁺] is a powerful scientific computing library built upon NumPy. It includes high-level tools for linear algebra, statistics, signal processing, integration, optimization, machine learning, and more.

SciPy can be imported with an alias (such as `sp` or `sc`) or without an alias, although typically in practice, specific modules are imported individually.¹

```
>>> import scipy as sp          # Import SciPy and give it an alias
>>> sp.stats.uniform()         # Calling functions will only import ←
     necessary modules

>>> import scipy              # No alias is required for SciPy
>>> scipy.stats.uniform()      # Calling functions will only import ←
     necessary modules

>>> from scipy import stats    # You can also import modules individually
>>> stats.uniform()
```

Linear Algebra

NumPy and SciPy both have a linear algebra module, each called `linalg`, but SciPy's module is the larger of the two. Some of SciPy's common `linalg` functions are listed below.

Function	Returns
<code>det()</code>	The determinant of a square matrix.
<code>eig()</code>	The eigenvalues and eigenvectors of a square matrix.
<code>inv()</code>	The inverse of an invertible matrix.
<code>norm()</code>	The norm of a vector or matrix norm of a matrix.
<code>solve()</code>	The solution to $Ax = b$ (the system need not be square).

This library also includes routines for computing matrix decompositions.

```
>>> from scipy import linalg as la

# Make a random matrix and a random vector.
>>> A = np.random.random((1000, 1000))
>>> b = np.random.random(1000)
```

¹SciPy modules like `linalg` are really *packages*, which are not initialized when SciPy is imported alone.

```
# Compute the LU decomposition of A, including pivots.
>>> L, P = la.lu_factor(A)

# Use the LU decomposition to solve Ax = b.
>>> x = la.lu_solve((L, P), b)

# Check that the solution is legitimate.
>>> np.allclose(A @ x, b)
True
```

As with NumPy, SciPy's routines are all highly optimized. However, some algorithms are, by nature, faster than others.

Problem 4. Write a function that times different `scipy.linalg` functions for solving square linear systems.

For various values of n , generate a random $n \times n$ matrix A and a random n -vector \mathbf{b} using `np.random.random()`. Time how long it takes to solve the system $A\mathbf{x} = \mathbf{b}$ with each of the following approaches:

1. Invert A with `la.inv()` and left-multiply the inverse to \mathbf{b} .
2. Use `la.solve()`.
3. Use `la.lu_factor()` and `la.lu_solve()` to solve the system with the LU decomposition.
4. Use `la.lu_factor()` and `la.lu_solve()`, but only time `la.lu_solve()` (not the time it takes to do the factorization with `la.lu_factor()`).

Plot the system size n versus the execution times. Use log scales if needed.

ACHTUNG!

Problem 4 demonstrates that computing a matrix inverse is computationally expensive. In fact, numerically inverting matrices is so costly that there is hardly ever a good reason to do it. Use a specific solver like `la.lu_solve()` whenever possible instead of using `la.inv()`.

Sparse Matrices

Large linear systems can have tens of thousands of entries. Storing the corresponding matrices in memory can be difficult: a $10^5 \times 10^5$ system requires around 40 GB to store in a NumPy array (4 bytes per entry $\times 10^{10}$ entries). This is well beyond the amount of RAM in a normal laptop.

In applications where systems of this size arise, it is often the case that the system is *sparse*, meaning that most of the entries of the matrix are 0. SciPy's `sparse` module provides tools for efficiently constructing and manipulating 1- and 2-D sparse matrices. A `sparse` matrix only stores the nonzero values and the positions of these values. For sufficiently sparse matrices, storing the matrix as a `sparse` matrix may only take megabytes, rather than gigabytes.

For example, diagonal matrices are sparse. Storing an $n \times n$ diagonal matrix in the naïve way means storing n^2 values in memory. It is more efficient to instead store the diagonal entries in a 1-D array of n values. In addition to using less storage space, this allows for much faster matrix operations: the standard algorithm to multiply a matrix by a diagonal matrix involves n^3 steps, but most of these are multiplying by or adding 0. A smarter algorithm can accomplish the same task much faster.

SciPy has seven sparse matrix types. Each type is optimized either for storing sparse matrices whose nonzero entries follow certain patterns, or for performing certain computations.

Name	Description	Advantages
<code>bsr_array</code>	Block Sparse Row	Specialized structure.
<code>coo_array</code>	Coordinate Format	Conversion among sparse formats.
<code>csc_array</code>	Compressed Sparse Column	Column-based operations and slicing.
<code>csr_array</code>	Compressed Sparse Row	Row-based operations and slicing.
<code>dia_array</code>	Diagonal Storage	Specialized structure.
<code>dok_array</code>	Dictionary of Keys	Element access, incremental construction.
<code>lil_array</code>	Row-based Linked List	Incremental construction.

Creating Sparse Matrices

A regular, non-sparse matrix is called *full* or *dense*. Full matrices can be converted to each of the sparse matrix formats listed above. However, it is more memory efficient to never create the full matrix in the first place. There are three main approaches for creating sparse matrices from scratch.

- **Coordinate Format:** When all of the nonzero values and their positions are known, create the entire sparse matrix at once as a `coo_array`. All nonzero values are stored as a coordinate and a value. This format also converts quickly to other sparse matrix types.

```
>>> from scipy import sparse

# Define the rows, columns, and values separately.
>>> rows = np.array([0, 1, 0])
>>> cols = np.array([0, 1, 1])
>>> vals = np.array([3, 5, 2])
>>> A = sparse.coo_array((vals, (rows, cols)), shape=(3, 3))
>>> print(A)
(0, 0)    3
(1, 1)    5
(0, 1)    2

# The toarray() method casts the sparse matrix as a NumPy array.
>>> print(A.toarray())                  # Note that this method forfeits
[[3 2 0]                      # all sparsity-related optimizations.
 [0 5 0]
 [0 0 0]]
```

- **DOK and LIL Formats:** If the matrix values and their locations are not known beforehand, construct the matrix incrementally with a `dok_array` or a `lil_array`. Indicate the size of the matrix, then change individual values with regular slicing syntax.

```
>>> B = sparse.lil_array((2, 6))
>>> B[0, 2] = 4
>>> B[1, 3:] = 9

>>> print(B.toarray())
[[ 0.  0.  4.  0.  0.  0.]
 [ 0.  0.  0.  9.  9.  9.]]
```

- **DIA Format:** Use a `dia_array` to store matrices that have nonzero entries on only certain diagonals. The function `sparse.diags()` is one convenient way to create a `dia_array` from scratch. Additionally, every sparse matrix has a `setdiags()` method for modifying specified diagonals.

```
# Use sparse.diags() to create a matrix with diagonal entries.
>>> diagonals = [[1, 2], [3, 4, 5], [6]]      # List the diagonal entries.
>>> offsets = [-1, 0, 3]                      # Specify the diagonal they go ←
                                                on.
>>> print(sparse.diags(diagonals, offsets, shape=(3, 4)).toarray())
[[ 3.  0.  0.  6.]
 [ 1.  4.  0.  0.]
 [ 0.  2.  5.  0.]]]

# If all of the diagonals have the same entry, specify the entry alone.
>>> A = sparse.diags([1, 3, 6], offsets, shape=(3, 4))
>>> print(A.toarray())
[[ 3.  0.  0.  6.]
 [ 1.  3.  0.  0.]
 [ 0.  1.  3.  0.]]]

# Modify a diagonal with the setdiag() method.
>>> A.setdiag([4, 4, 4], 0)
>>> print(A.toarray())
[[ 4.  0.  0.  6.]
 [ 1.  4.  0.  0.]
 [ 0.  1.  4.  0.]]
```

- **BSR Format:** Many sparse matrices can be formulated as block matrices, and a block matrix can be stored efficiently as a `bsr_array`. Use `sparse.bmat()` or `sparse.block_diag()` to create a block matrix quickly.

```
# Use sparse.bmat() to create a block matrix. Use 'None' for zero blocks.
>>> A = sparse.coo_array(np.ones((2, 2)))
>>> B = sparse.coo_array(np.full((2, 2), 2.))
>>> print(sparse.bmat([[ A , None, A ],
                           [None, B , None]], format='bsr').toarray())
[[ 1.  1.  0.  0.  1.  1.]
 [ 1.  1.  0.  0.  1.  1.]
```

```
[ 0.  0.  2.  2.  0.  0.]
[ 0.  0.  2.  2.  0.  0.]]
```

Use sparse.block_diag() to construct a block diagonal matrix.

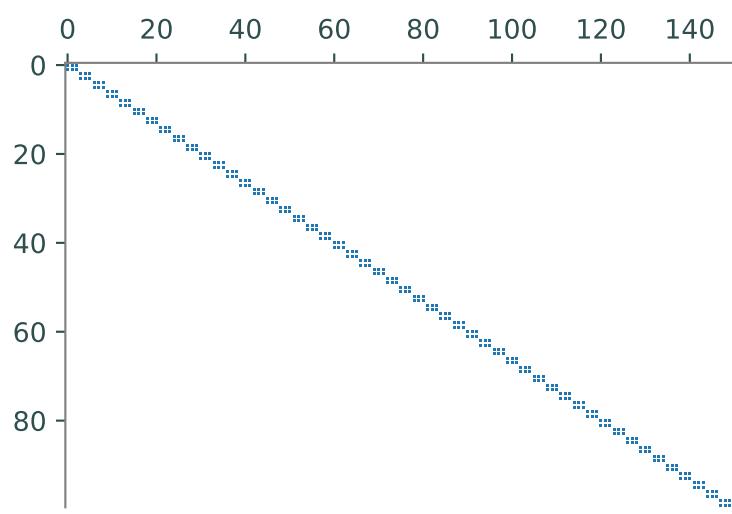

```
>>> print(sparse.block_diag((A, B)).toarray())
[[ 1.  1.  0.  0.]
 [ 1.  1.  0.  0.]
 [ 0.  0.  2.  2.]
 [ 0.  0.  2.  2.]]
```

NOTE

If a sparse matrix is too large to fit in memory as an array, it can still be visualized with Matplotlib's plt.spy(), which colors in the locations of the non-zero entries of the matrix.

```
>>> from matplotlib import pyplot as plt

# Construct and show a matrix with 50 2x3 diagonal blocks.
>>> B = sparse.coo_array([[1, 3, 5], [7, 9, 11]])
>>> A = sparse.block_diag([B]*50)
>>> plt.spy(A, markersize=1)
>>> plt.show()
```

Problem 5. Let I be the $n \times n$ identity matrix, and define

$$A = \begin{bmatrix} B & I \\ I & B & I \\ & I & \ddots & \ddots & \\ & & \ddots & \ddots & I \\ & & & I & B \end{bmatrix}, \quad B = \begin{bmatrix} -4 & 1 & & & \\ 1 & -4 & 1 & & \\ & 1 & \ddots & \ddots & \\ & & \ddots & \ddots & 1 \\ & & & 1 & -4 \end{bmatrix},$$

where A is $n^2 \times n^2$ and each block B is $n \times n$. The large matrix A is used in finite difference methods for solving Laplace's equation in two dimensions, $\frac{\partial^2 u}{\partial x^2} + \frac{\partial^2 u}{\partial y^2} = 0$.

Write a function that accepts an integer n and constructs and returns A as a sparse matrix. Use `plt.spy()` to check that your matrix has nonzero values in the correct places.

Sparse Matrix Operations

Once a sparse matrix has been constructed, it should be converted to a `csr_array` or a `csc_array` with the matrix's `tocsr()` or `tocsc()` method. The CSR and CSC formats are optimized for row or column operations, respectively. To choose the correct format to use, determine what direction the matrix will be traversed.

For example, in the matrix-matrix multiplication AB , A is traversed row-wise, but B is traversed column-wise. Thus A should be converted to a `csr_array` and B should be converted to a `csc_array`.

```
# Initialize a sparse matrix incrementally as a lil_array.
>>> A = sparse.lil_array((10000, 10000))
>>> for k in range(10000):
...     A[np.random.randint(0, 9999), np.random.randint(0, 9999)] = k
...
>>> A
<10000x10000 sparse matrix of type '<type 'numpy.float64'>'>
    with 9999 stored elements in LInked List format>

# Convert A to CSR and CSC formats to compute the matrix product AA.
>>> Acsr = A.tocsr()
>>> Acsc = A.tocsc()
>>> Acsr.dot(Acsc)
<10000x10000 sparse matrix of type '<type 'numpy.float64'>'>
    with 10142 stored elements in Compressed Sparse Row format>
```

Beware that row-based operations on a `csc_array` are very slow, and similarly, column-based operations on a `csr_array` are very slow.

ACHTUNG!

Many familiar NumPy operations have analogous routines in the `sparse` module. These methods take advantage of the sparse structure of the matrices and are, therefore, usually significantly faster. However, SciPy's `sparse` matrices behave a little differently than NumPy arrays.

Operation	<code>numpy</code>	<code>scipy.sparse</code>
Component-wise Addition	<code>A + B</code>	<code>A + B</code>
Scalar Multiplication	<code>2 * A</code>	<code>2 * A</code>
Component-wise Multiplication	<code>A * B</code>	<code>A.multiply(B)</code>
Matrix Multiplication	<code>A.dot(B), A @ B</code>	<code>A * B, A.dot(B), A @ B</code>

Note in particular the difference between `A * B` for NumPy arrays and SciPy sparse matrices. Do **not** use `np.dot()` to try to multiply sparse matrices, as it may treat the inputs incorrectly. The syntax `A.dot(B)` is safest in most cases.

SciPy's sparse module has its own linear algebra library, `scipy.sparse.linalg`, designed for operating on sparse matrices.

```
>>> from scipy.sparse import linalg as spla
```

Problem 6. Write a function that times regular and sparse linear system solvers.

For various values of n , generate the $n^2 \times n^2$ matrix A described in Problem 5 and a random vector \mathbf{b} with n^2 entries. Time how long it takes to solve the system $A\mathbf{x} = \mathbf{b}$ with each of the following approaches:

1. Convert A to CSR format and use `scipy.sparse.linalg.spsolve()` (`spla.spsolve()`).
2. Convert A to a NumPy array and use `scipy.linalg.solve()` (`la.solve()`).

In each experiment, only time how long it takes to solve the system (not how long it takes to convert A to the appropriate format).

Plot the system size n^2 versus the execution times. As always, use log scales where appropriate and use a legend to label each line.

ACHTUNG!

Even though there are fast algorithms for solving certain sparse linear systems, it is still very computationally difficult to invert sparse matrices. In fact, the inverse of a sparse matrix is usually not sparse. There is rarely a good reason to invert a matrix, sparse or dense.

See <http://docs.scipy.org/doc/scipy/reference/sparse.html> for additional details on SciPy's `sparse` module.

Additional Material

Improvements on the LU Decomposition

Vectorization

Algorithm 1 uses two loops to compute the LU decomposition. With a little vectorization, the process can be reduced to a single loop.

Algorithm 2

```

1: procedure FAST LU DECOMPOSITION( $A$ )
2:    $m, n \leftarrow \text{shape}(A)$ 
3:    $U \leftarrow \text{copy}(A)$ 
4:    $L \leftarrow I_m$ 
5:   for  $k = 0 \dots n - 1$  do
6:      $L_{k+1:,k} \leftarrow U_{k+1:,k} / U_{k,k}$ 
7:      $U_{k+1:,k:} \leftarrow U_{k+1:,k:} - L_{k+1:,k} U_{k,k:}^T$ 
8:   return  $L, U$ 
```

Note that step 7 is an *outer product*, not the regular dot product ($\mathbf{x}\mathbf{y}^T$ instead of the usual $\mathbf{x}^T\mathbf{y}$). Use `np.outer()` instead of `np.dot()` or `@` to get the desired result.

Pivoting

Gaussian elimination iterates through the rows of a matrix, using the diagonal entry $x_{k,k}$ of the matrix at the k th iteration to zero out all of the entries in the column below $x_{k,k}$ ($x_{i,k}$ for $i \geq k$). This diagonal entry is called the *pivot*. Unfortunately, Gaussian elimination, and hence the LU decomposition, can be very numerically unstable if at any step the pivot is a very small number. Most professional row reduction algorithms avoid this problem via *partial pivoting*.

The idea is to choose the largest number (in magnitude) possible to be the pivot by swapping the pivot row² with another row before operating on the matrix. For example, the second and fourth rows of the following matrix are exchanged so that the pivot is -6 instead of 2 .

$$\begin{bmatrix} \times & \times & \times & \times \\ 0 & 2 & \times & \times \\ 0 & 4 & \times & \times \\ 0 & -6 & \times & \times \end{bmatrix} \rightarrow \begin{bmatrix} \times & \times & \times & \times \\ 0 & -6 & \times & \times \\ 0 & 4 & \times & \times \\ 0 & 2 & \times & \times \end{bmatrix} \rightarrow \begin{bmatrix} \times & \times & \times & \times \\ 0 & -6 & \times & \times \\ 0 & 0 & \times & \times \\ 0 & 0 & \times & \times \end{bmatrix}$$

A row swap is equivalent to left-multiplying by a type II elementary matrix, also called a *permutation matrix*.

$$\begin{bmatrix} 1 & 0 & 0 & 0 \\ 0 & 0 & 0 & 1 \\ 0 & 0 & 1 & 0 \\ 0 & 1 & 0 & 0 \end{bmatrix} \begin{bmatrix} \times & \times & \times & \times \\ 0 & 2 & \times & \times \\ 0 & 4 & \times & \times \\ 0 & -6 & \times & \times \end{bmatrix} = \begin{bmatrix} \times & \times & \times & \times \\ 0 & -6 & \times & \times \\ 0 & 4 & \times & \times \\ 0 & 2 & \times & \times \end{bmatrix}$$

For the LU decomposition, if the permutation matrix at step k is P_k , then $P = P_k \dots P_2 P_1$ yields $PA = LU$. The complete algorithm is given below.

²Complete pivoting involves row and column swaps, but doing both operations is usually considered overkill.

Algorithm 3

```

1: procedure LU DECOMPOSITION WITH PARTIAL PIVOTING( $A$ )
2:    $m, n \leftarrow \text{shape}(A)$ 
3:    $U \leftarrow \text{copy}(A)$ 
4:    $L \leftarrow I_m$ 
5:    $P \leftarrow [0, 1, \dots, n - 1]$                                  $\triangleright$  See tip 2 below.
6:   for  $k = 0 \dots n - 1$  do
7:     Select  $i \geq k$  that maximizes  $|U_{i,k}|$ 
8:      $U_{k,k} \leftrightarrow U_{i,k}$                                  $\triangleright$  Swap the two rows.
9:      $L_{k,:k} \leftrightarrow L_{i,:k}$                                  $\triangleright$  Swap the two rows.
10:     $P_k \leftrightarrow P_i$                                  $\triangleright$  Swap the two entries.
11:     $L_{k+1:,k} \leftarrow U_{k+1:,k} / U_{k,k}$ 
12:     $U_{k+1:,k} \leftarrow U_{k+1:,k} - L_{k+1:,k} U_{k,k}^T$ 
13:   return  $L, U, P$ 

```

The following tips may be helpful for implementing this algorithm:

1. Since NumPy arrays are mutable, use `np.copy()` to reassign the rows of an array simultaneously.
2. Instead of storing P as an $n \times n$ array, fancy indexing allows us to encode row swaps in a 1-D array of length n . Initialize P as the array $[0, 1, \dots, n - 1]$. After performing a row swap on A , perform the same operations on P . Then the matrix product PA will be the same as $A[P]$.

```

>>> A = np.zeros(3) + np.vstack(np.arange(3))
>>> P = np.arange(3)
>>> print(A)
[[ 0.  0.  0.]
 [ 1.  1.  1.]
 [ 2.  2.  2.]]

# Swap rows 1 and 2.
>>> A[1], A[2] = np.copy(A[2]), np.copy(A[1])
>>> P[1], P[2] = P[2], P[1]
>>> print(A)                                     # A with the new row arrangement.
[[ 0.  0.  0.]
 [ 2.  2.  2.]
 [ 1.  1.  1.]]

>>> print(P)                                     # The permutation of the rows.
[0 2 1]
>>> print(A[P])                                 # A with the original row arrangement.
[[ 0.  0.  0.]
 [ 1.  1.  1.]
 [ 2.  2.  2.]]

```

There are potential cases where even partial pivoting does not eliminate catastrophic numerical errors in Gaussian elimination, but the odds of having such an amazingly poor matrix are essentially zero. The numerical analyst J.H. Wilkinson captured the likelihood of encountering such a matrix in a natural application when he said, “Anyone that unlucky has already been run over by a bus!”

In Place

The LU decomposition can be performed in place (overwriting the original matrix A) by storing U on and above the main diagonal of the array and storing L below it. The main diagonal of L does not need to be stored since all of its entries are 1. This format saves an entire array of memory, and is how `scipy.linalg.lu_factor()` returns the factorization.

More Applications of the LU Decomposition

The LU decomposition can also be used to compute inverses and determinants with relative efficiency.

- **Inverse:** $(PA)^{-1} = (LU)^{-1} \implies A^{-1}P^{-1} = U^{-1}L^{-1} \implies LUA^{-1} = P$. Solve $LUA_i = \mathbf{p}_i$ with forward and backward substitution (as in Problem 3) for every column \mathbf{p}_i of P . Then

$$A^{-1} = \left[\begin{array}{c|c|c|c} & & & \\ \mathbf{a}_1 & \mathbf{a}_2 & \cdots & \mathbf{a}_n \end{array} \right],$$

the matrix where \mathbf{a}_k is the k th column.

- **Determinant:** $\det(A) = \det(P^{-1}LU) = \frac{\det(L)\det(U)}{\det(P)}$. The determinant of a triangular matrix is the product of its diagonal entries. Since every diagonal entry of L is 1, $\det(L) = 1$. Also, P is just a row permutation of the identity matrix (which has determinant 1), and a single row swap negates the determinant. Then if S is the number of row swaps, the determinant is

$$\det(A) = (-1)^S \prod_{i=1}^n u_{ii}.$$

The Cholesky Decomposition

A square matrix A is called *positive definite* if $\mathbf{z}^\top A \mathbf{z} > 0$ for all nonzero vectors \mathbf{z} . In addition, A is called *Hermitian* if $A = A^\text{H} = \overline{A^\top}$. If A is Hermitian positive definite, it has a *Cholesky Decomposition* $A = U^\text{H}U$ where U is upper triangular with real, positive entries on the diagonal. This is the matrix equivalent to taking the square root of a positive real number.

The Cholesky decomposition takes advantage of the conjugate symmetry of A to simultaneously reduce the columns *and* rows of A to zeros (except for the diagonal). It thus requires only half of the calculations and memory of the LU decomposition. Furthermore, the algorithm is *numerically stable*, which means, roughly speaking, that round-off errors do not propagate throughout the computation.

Algorithm 4

```

1: procedure CHOLESKY DECOMPOSITION( $A$ )
2:    $n, n \leftarrow \text{shape}(A)$ 
3:    $U \leftarrow \text{np.triu}(A)$                                       $\triangleright$  Get the upper-triangular part of  $A$ .
4:   for  $i = 0 \dots n - 1$  do
5:     for  $j = i + 1 \dots n - 1$  do
6:        $U_{j,j:} \leftarrow U_{j,j:} - U_{i,j:} \overline{U_{ij}} / U_{ii}$ 
7:        $U_{i,i:} \leftarrow U_{i,i:} / \sqrt{U_{ii}}$ 
8:   return  $U$ 
```

As with the LU decomposition, SciPy's `linalg` module has optimized routines, `la.cho_factor()` and `la.cho_solve()`, for using the Cholesky decomposition.

4

The QR Decomposition

Lab Objective: The QR decomposition is a fundamentally important matrix factorization. It is straightforward to implement, is numerically stable, and provides the basis of several important algorithms. In this lab we explore several ways to produce the QR decomposition and implement a few immediate applications.

The QR decomposition of a matrix A is a factorization $A = QR$, where Q is has orthonormal columns and R is upper triangular. Every $m \times n$ matrix A of rank $n \leq m$ has a QR decomposition, with two main forms.

- **Reduced QR:** Q is $m \times n$, R is $n \times n$, and the columns $\{\mathbf{q}_j\}_{j=1}^n$ of Q form an orthonormal basis for the column space of A .
- **Full QR:** Q is $m \times m$ and R is $m \times n$. In this case, the columns $\{\mathbf{q}_j\}_{j=1}^m$ of Q form an orthonormal basis for all of \mathbb{F}^m , and the last $m - n$ rows of R only contain zeros. If $m = n$, this is the same as the reduced factorization.

We distinguish between these two forms by writing \hat{Q} and \hat{R} for the reduced decomposition and Q and R for the full decomposition.

$$\left[\begin{array}{c|ccccc} & & & & & \hat{Q} (m \times n) \\ \hline & \mathbf{q}_1 & \cdots & \mathbf{q}_n & \mathbf{q}_{n+1} & \cdots & \mathbf{q}_m \\ & & & & & & \\ & & & & & & \\ & & & & & & \\ & & & & & & \\ & & & & & & \\ & & & & & & \\ & & & & & & \\ Q (m \times m) & & & & & & \end{array} \right] \left[\begin{array}{ccc} r_{11} & \cdots & r_{1n} \\ \ddots & & \vdots \\ & & r_{nn} \\ 0 & \cdots & 0 \\ \vdots & & \vdots \\ 0 & \cdots & 0 \\ R (m \times n) & & & \end{array} \right] = A (m \times n)$$

QR via Gram-Schmidt

The *classical Gram-Schmidt algorithm* takes a linearly independent set of vectors and constructs an orthonormal set of vectors with the same span. Applying Gram-Schmidt to the columns of A , which are linearly independent since A has rank n , results in the columns of Q .

Let $\{\mathbf{x}_j\}_{j=1}^n$ be the columns of A . Define

$$\mathbf{q}_1 = \frac{\mathbf{x}_1}{\|\mathbf{x}_1\|}, \quad \mathbf{q}_k = \frac{\mathbf{x}_k - \mathbf{p}_{k-1}}{\|\mathbf{x}_k - \mathbf{p}_{k-1}\|}, \quad k = 2, \dots, n,$$

$$\mathbf{p}_0 = \mathbf{0}, \quad \mathbf{p}_{k-1} = \sum_{j=1}^{k-1} \langle \mathbf{q}_j, \mathbf{x}_k \rangle \mathbf{q}_j, \quad k = 2, \dots, n.$$

Each \mathbf{p}_{k-1} is the projection of \mathbf{x}_k onto the span of $\{\mathbf{q}_j\}_{j=1}^{k-1}$, so $\mathbf{q}'_k = \mathbf{x}_k - \mathbf{p}_{k-1}$ is the residual vector of the projection. Thus \mathbf{q}'_k is orthogonal to each of the vectors in $\{\mathbf{q}_j\}_{j=1}^{k-1}$. Therefore, normalizing each \mathbf{q}'_k produces an orthonormal set $\{\mathbf{q}_j\}_{j=1}^n$.

To construct the reduced QR decomposition, let \widehat{Q} be the matrix with columns $\{\mathbf{q}_j\}_{j=1}^n$, and let \widehat{R} be the upper triangular matrix with entries

$$r_{kk} = \|\mathbf{x}_k - \mathbf{p}_{k-1}\|, \quad r_{jk} = \langle \mathbf{q}_j, \mathbf{x}_k \rangle = \mathbf{q}_j^\top \mathbf{x}_k, \quad j < k.$$

This clever choice of entries for \widehat{R} reverses the Gram-Schmidt process and ensures that $\widehat{Q}\widehat{R} = A$.

Modified Gram-Schmidt

If the columns of A are close to being linearly dependent, the classical Gram-Schmidt algorithm often produces a set of vectors $\{\mathbf{q}_j\}_{j=1}^n$ that are not even close to orthonormal due to rounding errors. The *modified Gram-Schmidt algorithm* is a slight variant of the classical algorithm which more consistently produces a set of vectors that are “very close” to orthonormal.

Let \mathbf{q}_1 be the normalization of \mathbf{x}_1 as before. Instead of making just \mathbf{x}_2 orthogonal to \mathbf{q}_1 , make **each** of the vectors $\{\mathbf{x}_j\}_{j=2}^n$ orthogonal to \mathbf{q}_1 :

$$\mathbf{x}_k = \mathbf{x}_k - \langle \mathbf{q}_1, \mathbf{x}_k \rangle \mathbf{q}_1, \quad k = 2, \dots, n.$$

Next, define $\mathbf{q}_2 = \frac{\mathbf{x}_2}{\|\mathbf{x}_2\|}$. Proceed by making each of $\{\mathbf{x}_j\}_{j=3}^n$ orthogonal to \mathbf{q}_2 :

$$\mathbf{x}_k = \mathbf{x}_k - \langle \mathbf{q}_2, \mathbf{x}_k \rangle \mathbf{q}_2, \quad k = 3, \dots, n.$$

Since each of these new vectors is a linear combination of vectors orthogonal to \mathbf{q}_1 , they are orthogonal to \mathbf{q}_1 as well. Continuing this process results in the desired orthonormal set $\{\mathbf{q}_j\}_{j=1}^n$. The entire modified Gram-Schmidt algorithm is described below.

Algorithm 1

```

1: procedure MODIFIED GRAM-SCHMIDT( $A$ )
2:    $m, n \leftarrow \text{shape}(A)$                                       $\triangleright$  Store the dimensions of  $A$ .
3:    $Q \leftarrow \text{copy}(A)$                                           $\triangleright$  Make a copy of  $A$  with np.copy().
4:    $R \leftarrow \text{zeros}(n, n)$                                         $\triangleright$  An  $n \times n$  array of all zeros.
5:   for  $i = 0 \dots n - 1$  do
6:      $R_{i,i} \leftarrow \|Q_{:,i}\|$                                           $\triangleright$  Normalize the  $i$ th column of  $Q$ .
7:      $Q_{:,i} \leftarrow Q_{:,i}/R_{i,i}$ 
8:     for  $j = i + 1 \dots n - 1$  do
9:        $R_{i,j} \leftarrow Q_{:,j}^\top Q_{:,i}$ 
10:       $Q_{:,j} \leftarrow Q_{:,j} - R_{i,j}Q_{:,i}$                                  $\triangleright$  Orthogonalize the  $j$ th column of  $Q$ .
11:    return  $Q, R$ 

```

Problem 1. Write a function that accepts an $m \times n$ matrix A of rank n . Use Algorithm 1 to compute the reduced QR decomposition of A .

Consider the following tips for implementing the algorithm.

- Use `scipy.linalg.norm()` to compute the norm of the vector in step 6.
- Note that steps 7 and 10 employ scalar multiplication or division, while step 9 uses vector multiplication.

To test your function, generate test cases with NumPy's `np.random` module. Verify that R is upper triangular, Q is orthonormal, and $QR = A$. You may also want to compare your results to SciPy's QR factorization routine, `scipy.linalg.qr()`.

```
>>> import numpy as np
>>> from scipy import linalg as la

# Generate a random matrix and get its reduced QR decomposition via SciPy.
>>> A = np.random.random((6, 4))
>>> Q,R = la.qr(A, mode="economic") # Use mode="economic" for reduced QR.
>>> print(A.shape, Q.shape, R.shape)
(6, 4) (6, 4) (4, 4)

# Verify that R is upper triangular, Q is orthonormal, and QR = A.
>>> np.allclose(np.triu(R), R)
True
>>> np.allclose(Q.T @ Q, np.identity(4))
True
>>> np.allclose(Q @ R, A)
True
```

Consequences of the QR Decomposition

The special structures of Q and R immediately provide some simple applications.

Determinants

Let A be $n \times n$. Then Q and R are both $n \times n$ as well.¹ Since Q is orthonormal and R is upper-triangular,

$$\det(Q) = \pm 1 \quad \text{and} \quad \det(R) = \prod_{i=1}^n r_{i,i}.$$

Then since $\det(AB) = \det(A)\det(B)$,

$$|\det(A)| = |\det(QR)| = |\det(Q)\det(R)| = |\det(Q)||\det(R)| = \left| \prod_{i=1}^n r_{i,i} \right|. \quad (4.1)$$

¹An $n \times n$ orthonormal matrix is sometimes called *unitary* in other texts.

Problem 2. Write a function that accepts an invertible matrix A . Use the QR decomposition of A and (4.1) to calculate $|\det(A)|$. You may use your QR decomposition algorithm from Problem 1 or SciPy's QR routine. Can you implement this function in a single line?

(Hint: `np.diag()` and `np.prod()` may be useful.)

Check your answer against `la.det()`, which calculates the determinant.

Linear Systems

The LU decomposition is usually the matrix factorization of choice to solve the linear system $A\mathbf{x} = \mathbf{b}$ because the triangular structures of L and U facilitate forward and backward substitution. However, the QR decomposition avoids the potential numerical issues that come with Gaussian elimination.

Since Q is orthonormal, $Q^{-1} = Q^T$. Therefore, solving $A\mathbf{x} = \mathbf{b}$ is equivalent to solving the system $R\mathbf{x} = Q^T\mathbf{b}$. Since R is upper-triangular, $R\mathbf{x} = Q^T\mathbf{b}$ can be solved quickly with back substitution.²

Problem 3. Write a function that accepts an invertible $n \times n$ matrix A and a vector \mathbf{b} of length n . Use the QR decomposition to solve $A\mathbf{x} = \mathbf{b}$ in the following steps:

1. Compute Q and R .
2. Calculate $\mathbf{y} = Q^T\mathbf{b}$.
3. Use back substitution to solve $R\mathbf{x} = \mathbf{y}$ for \mathbf{x} .

QR via Householder

The Gram-Schmidt algorithm orthonormalizes A using a series of transformations that are stored in an upper triangular matrix. Another way to compute the QR decomposition is to take the opposite approach: triangularize A through a series of orthonormal transformations. Orthonormal transformations are numerically stable, meaning that they are less susceptible to rounding errors. In fact, this approach is usually faster and more accurate than Gram-Schmidt methods.

The idea is for the k th orthonormal transformation Q_k to map the k th column of A to the span of $\{\mathbf{e}_j\}_{j=1}^k$, where the \mathbf{e}_j are the standard basis vectors in \mathbb{R}^m . In addition, to preserve the work of the previous transformations, Q_k should not modify any entries of A that are above or to the left of the k th diagonal term of A . For a 4×3 matrix A , the process can be visualized as follows.

$$Q_3 Q_2 Q_1 \begin{bmatrix} * & * & * \\ * & * & * \\ * & * & * \\ * & * & * \end{bmatrix} = Q_3 Q_2 \begin{bmatrix} * & * & * \\ 0 & * & * \\ 0 & * & * \\ 0 & * & * \end{bmatrix} = Q_3 \begin{bmatrix} * & * & * \\ 0 & * & * \\ 0 & 0 & * \\ 0 & 0 & * \end{bmatrix} = \begin{bmatrix} * & * & * \\ 0 & * & * \\ 0 & 0 & * \\ 0 & 0 & 0 \end{bmatrix}$$

Thus $Q_3 Q_2 Q_1 A = R$, so that $A = Q_1^T Q_2^T Q_3^T R$ since each Q_k is orthonormal. Furthermore, the product of square orthonormal matrices is orthonormal, so setting $Q = Q_1^T Q_2^T Q_3^T$ yields the full QR decomposition.

How to correctly construct each Q_k isn't immediately obvious. The ingenious solution lies in one of the basic types of linear transformations: reflections.

²See the Linear Systems lab for details on back substitution.

Householder Transformations

The *orthogonal complement* of a nonzero vector $\mathbf{v} \in \mathbb{R}^n$ is the set of all vectors $\mathbf{x} \in \mathbb{R}^n$ that are orthogonal to \mathbf{v} , denoted $\mathbf{v}^\perp = \{\mathbf{x} \in \mathbb{R}^n \mid \langle \mathbf{x}, \mathbf{v} \rangle = 0\}$. A *Householder transformation* is a linear transformation that reflects a vector \mathbf{x} across the orthogonal complement \mathbf{v}^\perp for some specified \mathbf{v} .

The matrix representation of the Householder transformation corresponding to \mathbf{v} is given by $H_{\mathbf{v}} = I - 2\frac{\mathbf{v}\mathbf{v}^\top}{\mathbf{v}^\top \mathbf{v}}$. Since $H_{\mathbf{v}}^\top H_{\mathbf{v}} = I$, Householder transformations are orthonormal.

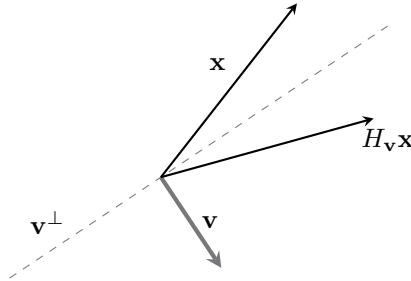

Figure 4.1: The vector \mathbf{v} defines the orthogonal complement \mathbf{v}^\perp , which in this case is a line. Applying the Householder transformation $H_{\mathbf{v}}$ to \mathbf{x} reflects \mathbf{x} across \mathbf{v}^\perp .

Householder Triangularization

The *Householder algorithm* uses Householder transformations for the orthonormal transformations in the QR decomposition process described on the previous page. The goal in choosing Q_k is to send \mathbf{x}_k , the k th column of A , to the span of $\{\mathbf{e}_j\}_{j=1}^k$. In other words, if $Q_k \mathbf{x}_k = \mathbf{y}_k$, the last $m-k$ entries of \mathbf{y}_k should be 0, i.e.,

$$Q_k \mathbf{x}_k = Q_k \begin{bmatrix} z_1 \\ \vdots \\ z_k \\ z_{k+1} \\ \vdots \\ z_m \end{bmatrix} = \begin{bmatrix} y_1 \\ \vdots \\ y_k \\ 0 \\ \vdots \\ 0 \end{bmatrix} = \mathbf{y}_k.$$

To begin, decompose \mathbf{x}_k into $\mathbf{x}_k = \mathbf{x}'_k + \mathbf{x}''_k$, where \mathbf{x}'_k and \mathbf{x}''_k are of the form

$$\mathbf{x}'_k = [z_1 \quad \cdots \quad z_{k-1} \quad 0 \quad \cdots \quad 0]^\top, \quad \mathbf{x}''_k = [0 \quad \cdots \quad 0 \quad z_k \quad \cdots \quad z_m]^\top.$$

Because \mathbf{x}'_k represents elements of A that lie above the diagonal, only \mathbf{x}''_k needs to be altered by the reflection.

The two vectors $\mathbf{x}''_k \pm \|\mathbf{x}''_k\| \mathbf{e}_k$ both yield Householder transformations that send \mathbf{x}''_k to the span of \mathbf{e}_k (see Figure 4.2). Between the two, the one that reflects \mathbf{x}''_k further is more numerically stable. This reflection corresponds to

$$\mathbf{v}_k = \mathbf{x}''_k + \text{sign}(z_k) \|\mathbf{x}''_k\| \mathbf{e}_k,$$

where z_k is the first nonzero component of \mathbf{x}''_k (the k th component of \mathbf{x}_k).

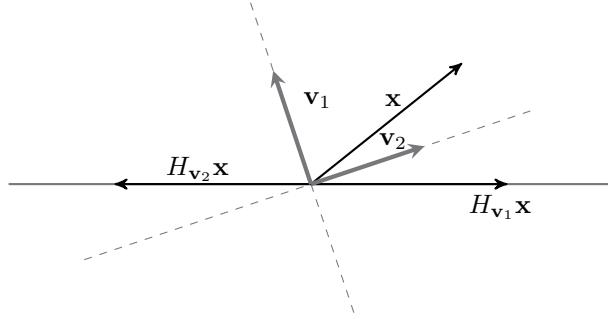

Figure 4.2: There are two reflections that map \mathbf{x} into the span of \mathbf{e}_1 , defined by the vectors \mathbf{v}_1 and \mathbf{v}_2 . In this illustration, $H_{\mathbf{v}_2}$ is the more stable transformation since it reflects \mathbf{x} further than $H_{\mathbf{v}_1}$.

After choosing \mathbf{v}_k , set $\mathbf{u}_k = \frac{\mathbf{v}_k}{\|\mathbf{v}_k\|}$. Then $H_{\mathbf{v}_k} = I - 2\frac{\mathbf{v}_k\mathbf{v}_k^\top}{\|\mathbf{v}_k\|^2} = I - 2\mathbf{u}_k\mathbf{u}_k^\top$, and hence Q_k is given by the block matrix

$$Q_k = \begin{bmatrix} I_{k-1} & \mathbf{0} \\ \mathbf{0} & H_{\mathbf{v}_k} \end{bmatrix} = \begin{bmatrix} I_{k-1} & \mathbf{0} \\ \mathbf{0} & I_{m-k+1} - 2\mathbf{u}_k\mathbf{u}_k^\top \end{bmatrix}.$$

Here I_p denotes the $p \times p$ identity matrix, and thus each Q_k is $m \times m$.

It is apparent from its form that Q_k does not affect the first $k - 1$ rows and columns of any matrix that it acts on. Then by starting with $R = A$ and $Q = I$, at each step of the algorithm we need only multiply the entries in the lower right $(m - k + 1) \times (m - k + 1)$ submatrices of R and Q by $I - 2\mathbf{u}_k\mathbf{u}_k^\top$. This completes the Householder algorithm, detailed below.

Algorithm 2

```

1: procedure HOUSEHOLDER( $A$ )
2:    $m, n \leftarrow \text{shape}(A)$ 
3:    $R \leftarrow \text{copy}(A)$ 
4:    $Q \leftarrow I_m$                                  $\triangleright$  The  $m \times m$  identity matrix.
5:   for  $k = 0 \dots n - 1$  do
6:      $\mathbf{u} \leftarrow \text{copy}(R_{k:,k})$ 
7:      $u_0 \leftarrow u_0 + \text{sign}(u_0)\|\mathbf{u}\|$            $\triangleright u_0$  is the first entry of  $\mathbf{u}$ .
8:      $\mathbf{u} \leftarrow \mathbf{u}/\|\mathbf{u}\|$                        $\triangleright$  Normalize  $\mathbf{u}$ .
9:      $R_{k:,k} \leftarrow R_{k:,k} - 2\mathbf{u}(\mathbf{u}^\top R_{k:,k})$      $\triangleright$  Apply the reflection to  $R$ .
10:     $Q_{k,:} \leftarrow Q_{k,:} - 2\mathbf{u}(\mathbf{u}^\top Q_{k,:})$          $\triangleright$  Apply the reflection to  $Q$ .
11:   return  $Q^\top, R$ 

```

Problem 4. Write a function that accepts as input a $m \times n$ matrix A of rank n . Use Algorithm 2 to compute the full QR decomposition of A .

Consider the following implementation details.

- NumPy's `np.sign()` is an easy way to implement the `sign()` operation in step 7. However, `np.sign(0)` returns 0, which will cause a problem in the rare case that $u_0 = 0$ (which is possible if the top left entry of A is 0 to begin with). The following code defines a function that returns the sign of a single number, counting 0 as positive.

```
sign = lambda x: 1 if x >= 0 else -1
```

- In steps 9 and 10, the multiplication of \mathbf{u} and $(\mathbf{u}^T X)$ is an *outer product* ($\mathbf{x}\mathbf{y}^T$ instead of the usual $\mathbf{x}^T\mathbf{y}$). Use `np.outer()` instead of `np.dot()` to handle this correctly.

Use NumPy and SciPy to generate test cases and validate your function.

```
>>> A = np.random.random((5, 3))
>>> Q,R = la.qr(A)                      # Get the full QR decomposition.
>>> print(A.shape, Q.shape, R.shape)
(5, 3) (5, 5) (5, 3)
>>> np.allclose(Q @ R, A)
True
```

Upper Hessenberg Form

An *upper Hessenberg matrix* is a square matrix that is nearly upper triangular, with zeros below the first subdiagonal. Every $n \times n$ matrix A can be written $A = QHQ^T$ where Q is orthonormal and H , called the *Hessenberg form* of A , is an upper Hessenberg matrix. Putting a matrix in upper Hessenberg form is an important first step to computing its eigenvalues numerically.

This algorithm also uses Householder transformations. To find orthogonal Q and upper Hessenberg H such that $A = QHQ^T$, it suffices to find such matrices that satisfy $Q^TAQ = H$. Thus, the strategy is to multiply A on the left and right by a series of orthonormal matrices until it is in Hessenberg form.

Using the same Q_k as in the k th step of the Householder algorithm introduces $n - k$ zeros in the k th column of A , but multiplying Q_kA on the right by Q_k^T destroys all of those zeros. Instead, choose a Q_1 that fixes \mathbf{e}_1 and reflects the first column of A into the span of \mathbf{e}_1 and \mathbf{e}_2 . The product Q_1A then leaves the first row of A alone, and the product $(Q_1A)Q_1^T$ leaves the first column of (Q_1A) alone.

$$\begin{array}{c} \left[\begin{array}{cccccc} * & * & * & * & * \\ * & * & * & * & * \\ * & * & * & * & * \\ * & * & * & * & * \\ * & * & * & * & * \end{array} \right] \xrightarrow{Q_1} \left[\begin{array}{cccccc} * & * & * & * & * \\ * & * & * & * & * \\ 0 & * & * & * & * \\ 0 & * & * & * & * \\ 0 & * & * & * & * \end{array} \right] \xrightarrow{Q_1^T} \left[\begin{array}{ccccc} * & * & * & * & * \\ * & * & * & * & * \\ 0 & * & * & * & * \\ 0 & * & * & * & * \\ 0 & * & * & * & * \end{array} \right] \\ A \qquad \qquad \qquad Q_1A \qquad \qquad \qquad (Q_1A)Q_1^T \end{array}$$

Continuing the process results in the upper Hessenberg form of A .

$$Q_3Q_2Q_1AQ_1^TQ_2^TQ_3^T = \left[\begin{array}{ccccc} * & * & * & * & * \\ * & * & * & * & * \\ 0 & * & * & * & * \\ 0 & 0 & * & * & * \\ 0 & 0 & 0 & * & * \end{array} \right]$$

This implies that $A = Q_1^TQ_2^TQ_3^THQ_3Q_2Q_1$, so setting $Q = Q_1^TQ_2^TQ_3^T$ results in the desired factorization $A = QHQ^T$.

Constructing the Reflections

Constructing the Q_k uses the same approach as in the Householder algorithm, but shifted down one element. Let $\mathbf{x}_k = \mathbf{y}'_k + \mathbf{y}''_k$ where \mathbf{y}'_k and \mathbf{y}''_k are of the form

$$\mathbf{y}'_k = [z_1 \ \cdots \ z_k \ 0 \ \cdots \ 0]^\top, \quad \mathbf{y}''_k = [0 \ \cdots \ 0 \ z_{k+1} \ \cdots \ z_m]^\top.$$

Because \mathbf{y}'_k represents elements of A that lie above the first subdiagonal, only \mathbf{y}''_k needs to be altered. This suggests using the reflection

$$Q_k = \begin{bmatrix} I_k & \mathbf{0} \\ \mathbf{0} & H_{\mathbf{v}_k} \end{bmatrix} = \begin{bmatrix} I_k & \mathbf{0} \\ \mathbf{0} & I_{m-k} - 2\mathbf{u}_k\mathbf{u}_k^\top \end{bmatrix}, \text{ where}$$

$$\mathbf{v}_k = \mathbf{y}''_k + \text{sign}(z_k)\|\mathbf{y}''_k\|\mathbf{e}_k, \quad \mathbf{u}_k = \frac{\mathbf{v}_k}{\|\mathbf{v}_k\|}.$$

The complete algorithm is given below. Note how similar it is to Algorithm 2.

Algorithm 3

```

1: procedure HESSENBERG( $A$ )
2:    $m, n \leftarrow \text{shape}(A)$ 
3:    $H \leftarrow \text{copy}(A)$ 
4:    $Q \leftarrow I_m$ 
5:   for  $k = 0 \dots n - 3$  do
6:      $\mathbf{u} \leftarrow \text{copy}(H_{k+1:,k})$ 
7:      $u_0 \leftarrow u_0 + \text{sign}(u_0)\|\mathbf{u}\|$ 
8:      $\mathbf{u} \leftarrow \mathbf{u}/\|\mathbf{u}\|$ 
9:      $H_{k+1:,k} \leftarrow H_{k+1:,k} - 2\mathbf{u}(\mathbf{u}^\top H_{k+1:,k})$   $\triangleright$  Apply  $Q_k$  to  $H$ .
10:     $H_{:,k+1} \leftarrow H_{:,k+1} - 2(H_{:,k+1} \mathbf{u})\mathbf{u}^\top$   $\triangleright$  Apply  $Q_k^\top$  to  $H$ .
11:     $Q_{k+1,:} \leftarrow Q_{k+1,:} - 2\mathbf{u}(\mathbf{u}^\top Q_{k+1,:})$   $\triangleright$  Apply  $Q_k$  to  $Q$ .
12:   return  $H, Q^\top$ 

```

Problem 5. Write a function that accepts a nonsingular $n \times n$ matrix A . Use Algorithm 3 to compute the upper Hessenberg H and orthogonal Q satisfying $A = QHQ^\top$.

Compare your results to `scipy.linalg.hessenberg()`.

```

# Generate a random matrix and get its upper Hessenberg form via SciPy.
>>> A = np.random.random((8, 8))
>>> H, Q = la.hessenberg(A, calc_q=True)

# Verify that H has all zeros below the first subdiagonal and QHQ\trp = A<-
.
>>> np.allclose(np.triu(H, -1), H)
True
>>> np.allclose(Q @ H @ Q.T, A)
True

```

Additional Material

Complex QR Decomposition

The QR decomposition also exists for matrices with complex entries. The standard inner product in \mathbb{R}^m is $\langle \mathbf{x}, \mathbf{y} \rangle = \mathbf{x}^T \mathbf{y}$, but the (more general) standard inner product in \mathbb{C}^m is $\langle \mathbf{x}, \mathbf{y} \rangle = \mathbf{x}^H \mathbf{y}$. The H stands for the *Hermitian conjugate*, the conjugate of the transpose. Making a few small adjustments in the implementations of Algorithms 1 and 2 accounts for using the complex inner product.

1. Replace any transpose operations with the conjugate of the transpose.

```
>>> A = np.reshape(np.arange(4) + 1j*np.arange(4), (2, 2))
>>> print(A)
[[ 0.+0.j  1.+1.j]
 [ 2.+2.j  3.+3.j]]

>>> print(A.T)                                     # Regular transpose.
[[ 0.+0.j  2.+2.j]
 [ 1.+1.j  3.+3.j]]

>>> print(A.conj().T)                            # Hermitian conjugate.
[[ 0.-0.j  2.-2.j]
 [ 1.-1.j  3.-3.j]]
```

2. Conjugate the first entry of vector or matrix multiplication before multiplying with `np.dot()`.

```
>>> x = np.arange(2) + 1j*np.arange(2)
>>> print(x)
[ 0.+0.j  1.+1.j]

>>> np.dot(x, x)                                # Standard real inner product.
2j

>>> np.dot(x.conj(), y)                         # Standard complex inner product.
(2 + 0j)
```

3. In the complex plane, there are infinitely many reflections that map a vector \mathbf{x} into the span of \mathbf{e}_k , not just the two displayed in Figure 4.2. Using $\text{sign}(z_k)$ to choose one is still a valid method, but it requires updating the `sign()` function so that it can handle complex numbers.

```
sign = lambda x: x/np.abs(x) if x!=0 else 1
```

QR with Pivoting

The LU decomposition can be improved by employing Gaussian elimination with partial pivoting, where the rows of A are strategically permuted at each iteration. The QR factorization can be similarly improved by permuting the columns of A at each iteration. The result is the factorization $AP = QR$, where P is a permutation matrix that encodes the column swaps. To compute the pivoted QR decomposition with `scipy.linalg.qr()`, set the keyword `pivoting` to `True`.

```
# Get the decomposition AP = QR for a random matrix A.
>>> A = np.random.random((8, 10))
>>> Q, R, P = la.qr(A, pivoting=True)

# P is returned as a 1-D array that encodes column ordering,
# so A can be reconstructed with fancy indexing.
>>> np.allclose(Q @ R, A[:, P])
True
```

QR via Givens

The Householder algorithm uses reflections to triangularize A . However, A can also be made upper triangular using rotations. To illustrate the idea, recall that the matrix for a counterclockwise rotation of θ radians is given by

$$R_\theta = \begin{bmatrix} \cos \theta & -\sin \theta \\ \sin \theta & \cos \theta \end{bmatrix}.$$

This transformation is orthonormal. Given $\mathbf{x} = [a, b]^\top$, if θ is the angle between \mathbf{x} and \mathbf{e}_1 , then $R_{-\theta}$ maps \mathbf{x} to the span of \mathbf{e}_1 .

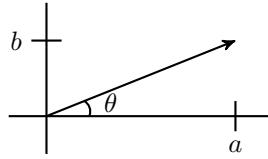

Figure 4.3: Rotating clockwise by θ sends the vector $[a, b]^\top$ to the span of \mathbf{e}_1 .

In terms of a and b , $\cos \theta = \frac{a}{\sqrt{a^2+b^2}}$ and $\sin \theta = \frac{b}{\sqrt{a^2+b^2}}$. Therefore,

$$R_{-\theta} \mathbf{x} = \begin{bmatrix} \cos \theta & \sin \theta \\ -\sin \theta & \cos \theta \end{bmatrix} \begin{bmatrix} a \\ b \end{bmatrix} = \begin{bmatrix} \frac{a}{\sqrt{a^2+b^2}} & \frac{b}{\sqrt{a^2+b^2}} \\ -\frac{b}{\sqrt{a^2+b^2}} & \frac{a}{\sqrt{a^2+b^2}} \end{bmatrix} \begin{bmatrix} a \\ b \end{bmatrix} = \begin{bmatrix} \sqrt{a^2+b^2} \\ 0 \end{bmatrix}.$$

The matrix R_θ above is an example of a 2×2 *Givens rotation matrix*. In general, the Givens matrix $G(i, j, \theta)$ represents the orthonormal transformation that rotates the 2-dimensional span of \mathbf{e}_i and \mathbf{e}_j by θ radians. The matrix representation of this transformation is a generalization of R_θ .

$$G(i, j, \theta) = \begin{bmatrix} I & 0 & 0 & 0 & 0 \\ 0 & c & 0 & -s & 0 \\ 0 & 0 & I & 0 & 0 \\ 0 & s & 0 & c & 0 \\ 0 & 0 & 0 & 0 & I \end{bmatrix}$$

Here I represents the identity matrix, $c = \cos \theta$, and $s = \sin \theta$. The c 's appear on the i th and j th diagonal entries.

Givens Triangularization

As demonstrated, θ can be chosen such that $G(i, j, \theta)$ rotates a vector so that its j th-component is 0. Such a transformation will only affect the i th and j th entries of any vector it acts on (and thus the i th and j th rows of any matrix it acts on).

To compute the QR decomposition of A , iterate through the subdiagonal entries of A in the order depicted by Figure 4.4. Zero out the ij th entry with a rotation in the plane spanned by \mathbf{e}_{i-1} and \mathbf{e}_i , represented by the Givens matrix $G(i-1, i, \theta)$.

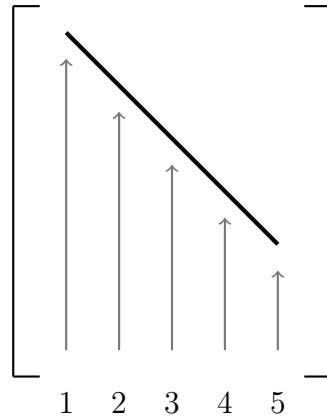

Figure 4.4: The order in which to zero out subdiagonal entries in the Givens triangularization algorithm. The heavy black line is the main diagonal of the matrix. Entries should be zeroed out from bottom to top in each column, beginning with the leftmost column.

On a 2×3 matrix, the process can be visualized as follows.

$$\left[\begin{array}{cc} * & * \\ * & * \\ * & * \end{array} \right] \xrightarrow{G(2,3,\theta_1)} \left[\begin{array}{cc} * & * \\ * & * \\ 0 & * \end{array} \right] \xrightarrow{G(1,2,\theta_2)} \left[\begin{array}{cc} * & * \\ 0 & * \\ 0 & * \end{array} \right] \xrightarrow{G(2,3,\theta_3)} \left[\begin{array}{cc} * & * \\ 0 & * \\ 0 & 0 \end{array} \right]$$

At each stage, the boxed entries are those modified by the previous transformation. The final transformation $G(2,3,\theta_3)$ operates on the bottom two rows, but since the first two entries are zero, they are unaffected.

Assuming that at the ij th stage of the algorithm a_{ij} is nonzero, Algorithm 4 computes the Givens triangularization of a matrix. Notice that the algorithm does not actually form the entire matrices $G(i, j, \theta)$; instead, it modifies only those entries of the matrix that are affected by the transformation.

Algorithm 4

```

1: procedure GIVENS TRIANGULARIZATION( $A$ )
2:    $m, n \leftarrow \text{shape}(A)$ 
3:    $R \leftarrow \text{copy}(A)$ 
4:    $Q \leftarrow I_m$ 
5:   for  $j = 0 \dots n - 1$  do
6:     for  $i = m - 1 \dots j + 1$  do
7:        $a, b \leftarrow R_{i-1,j}, R_{i,j}$ 
8:        $G \leftarrow [[a, b], [-b, a]] / \sqrt{a^2 + b^2}$ 
9:        $R_{i-1:i+1,j:} \leftarrow G R_{i-1:i+1,j:}$ 
10:       $Q_{i-1:i+1,:} \leftarrow G Q_{i-1:i+1,:}$ 
11:   return  $Q^T, R$ 

```

QR of a Hessenberg Matrix via Givens

The Givens algorithm is particularly efficient for computing the QR decomposition of a matrix that is already in upper Hessenberg form, since only the first subdiagonal needs to be zeroed out. Algorithm 5 details this process.

Algorithm 5

```

1: procedure GIVENS TRIANGULARIZATION OF HESSENBERG( $H$ )
2:    $m, n \leftarrow \text{shape}(H)$ 
3:    $R \leftarrow \text{copy}(H)$ 
4:    $Q \leftarrow I_m$ 
5:   for  $j = 0 \dots \min\{n - 1, m - 1\}$  do
6:      $i = j + 1$ 
7:      $a, b \leftarrow R_{i-1,j}, R_{i,j}$ 
8:      $G \leftarrow [[a, b], [-b, a]] / \sqrt{a^2 + b^2}$ 
9:      $R_{i-1:i+1,j:} \leftarrow G R_{i-1:i+1,j:}$ 
10:     $Q_{i-1:i+1,:i+1} \leftarrow G Q_{i-1:i+1,:i+1}$ 
11:  return  $Q^T, R$ 

```

NOTE

When A is symmetric, its upper Hessenberg form is a *tridiagonal* matrix, meaning its only nonzero entries are on the main diagonal, the first subdiagonal, and the first superdiagonal. This is because the Q_k 's zero out everything below the first subdiagonal of A and the Q_k^T 's zero out everything to the right of the first superdiagonal. Tridiagonal matrices make computations fast, so computing the Hessenberg form of a symmetric matrix is very useful.

5

Least Squares and Computing Eigenvalues

Lab Objective: *Because of its numerical stability and convenient structure, the QR decomposition is the basis of many important and practical algorithms. In this lab we introduce linear least squares problems, tools in Python for computing least squares solutions, and two fundamental algorithms for computing eigenvalues. The QR decomposition makes solving several of these problems quick and numerically stable.*

Least Squares

A linear system $A\mathbf{x} = \mathbf{b}$ is *overdetermined* if it has more equations than unknowns. In this situation, there is no true solution, and \mathbf{x} can only be approximated.

The *least squares solution* of $A\mathbf{x} = \mathbf{b}$, denoted $\hat{\mathbf{x}}$, is the “closest” vector to a solution, meaning it minimizes the quantity $\|A\hat{\mathbf{x}} - \mathbf{b}\|_2$. In other words, $\hat{\mathbf{x}}$ is the vector such that $A\hat{\mathbf{x}}$ is the projection of \mathbf{b} onto the range of A , and can be calculated by solving the *normal equations*,¹

$$A^\top A\hat{\mathbf{x}} = A^\top \mathbf{b}.$$

If A is full rank (which it usually is in applications) its QR decomposition provides an efficient way to solve the normal equations. Let $A = \widehat{Q}\widehat{R}$ be the reduced QR decomposition of A , so \widehat{Q} is $m \times n$ with orthonormal columns and \widehat{R} is $n \times n$, invertible, and upper triangular. Since $\widehat{Q}^\top \widehat{Q} = I$, and since \widehat{R}^\top is invertible, the normal equations can be reduced as follows (we omit the hats on \widehat{Q} and \widehat{R} for clarity).

$$\begin{aligned} A^\top A\hat{\mathbf{x}} &= A^\top \mathbf{b} \\ (QR)^\top QR\hat{\mathbf{x}} &= (QR)^\top \mathbf{b} \\ R^\top Q^\top QR\hat{\mathbf{x}} &= R^\top Q^\top \mathbf{b} \\ R^\top R\hat{\mathbf{x}} &= R^\top Q^\top \mathbf{b} \\ R\hat{\mathbf{x}} &= Q^\top \mathbf{b} \end{aligned} \tag{5.1}$$

Thus $\hat{\mathbf{x}}$ is the least squares solution to $A\mathbf{x} = \mathbf{b}$ if and only if $R\hat{\mathbf{x}} = Q^\top \mathbf{b}$. Since R is upper triangular, this equation can be solved quickly with back substitution.

¹See Volume 1 for a formal derivation of the normal equations.

Problem 1. Write a function that accepts an $m \times n$ matrix A of rank n and a vector \mathbf{b} of length m . Use the reduced QR decomposition of A and (5.1) to solve the normal equations corresponding to $A\mathbf{x} = \mathbf{b}$.

You may use either SciPy's reduced QR routine (`la.qr()` with `mode="economic"`) or one of your own reduced QR routines. In addition, you may use `la.solve_triangular()`, SciPy's optimized routine for solving triangular systems.

Fitting a Line

The least squares solution can be used to find the best fit curve of a chosen type to a set of points. Consider the problem of finding the line $y = ax + b$ that best fits a set of m points $\{(x_k, y_k)\}_{k=1}^m$. Ideally, we seek a and b such that $y_k = ax_k + b$ for all k . These equations can be simultaneously represented by the linear system

$$A\mathbf{x} = \begin{bmatrix} x_1 & 1 \\ x_2 & 1 \\ x_3 & 1 \\ \vdots & \vdots \\ x_m & 1 \end{bmatrix} \begin{bmatrix} a \\ b \end{bmatrix} = \begin{bmatrix} y_1 \\ y_2 \\ y_3 \\ \vdots \\ y_m \end{bmatrix} = \mathbf{b}. \quad (5.2)$$

Note that A has full column rank as long as not all of the x_k values are the same.

Because this system has two unknowns, it is guaranteed to have a solution if it has two or fewer equations. However, if there are more than two data points, the system is overdetermined if any set of three points is not collinear. We therefore seek a least squares solution, which in this case means finding the slope \hat{a} and y -intercept \hat{b} such that the line $y = \hat{a}x + \hat{b}$ best fits the data.

Figure 5.1 is a typical example of this idea where $\hat{a} \approx \frac{1}{2}$ and $\hat{b} \approx -3$.

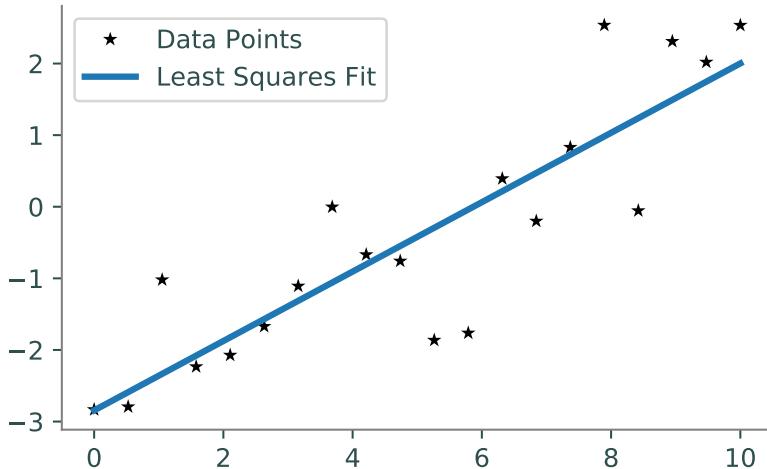

Figure 5.1: A linear least squares fit.

Problem 2. The file `housing.npy` contains the purchase-only housing price index, a measure of how housing prices are changing, for the United States from 2000 to 2016.^a Each row in the array is a separate measurement; the columns are the year and the price index, in that order. To avoid large numerical computations, the year measurements start at 0 instead of 2000.

Find the least squares line that relates the year to the housing price index (i.e., let year be the x -axis and index the y -axis).

1. Construct the matrix A and the vector \mathbf{b} described by (5.2).
(Hint: `np.vstack()`, `np.column_stack()`, and/or `np.ones()` may be helpful.)
2. Use your function from Problem 1 to find the least squares solution.
3. Plot the data points as a scatter plot.
4. Plot the least squares line with the scatter plot.

^aSee <http://www.fhfa.gov/DataTools/Downloads/Pages/House-Price-Index.aspx>.

NOTE

The least squares problem of fitting a line to a set of points is often called *linear regression*, and the resulting line is called the *linear regression line*. SciPy's specialized tool for linear regression is `scipy.stats.linregress()`. This function takes in an array of x -coordinates and a corresponding array of y -coordinates, and returns the slope and intercept of the regression line, along with a few other statistical measurements.

For example, the following code produces Figure 5.1.

```
>>> import numpy as np
>>> from scipy.stats import linregress

# Generate some random data close to the line y = .5x - 3.
>>> x = np.linspace(0, 10, 20)
>>> y = .5*x - 3 + np.random.randn(20)

# Use linregress() to calculate m and b, as well as the correlation
# coefficient, p-value, and standard error. See the documentation for
# details on each of these extra return values.
>>> a, b, rvalue, pvalue, stderr = linregress(x, y)

>>> plt.plot(x, y, 'k*', label="Data Points")
>>> plt.plot(x, a*x + b, label="Least Squares Fit")
>>> plt.legend(loc="upper left")
>>> plt.show()
```

Fitting a Polynomial

Least squares can also be used to fit a set of data to the best fit polynomial of a specified degree. Let $\{(x_k, y_k)\}_{k=1}^m$ be the set of m data points in question. The general form for a polynomial of degree n is

$$p_n(x) = c_n x^n + c_{n-1} x^{n-1} + \cdots + c_2 x^2 + c_1 x + c_0 = \sum_{i=0}^n c_i x^i.$$

Note that the polynomial is uniquely determined by its $n+1$ coefficients $\{c_i\}_{i=0}^n$. Ideally, then, we seek the set of coefficients $\{c_i\}_{i=0}^n$ such that

$$y_k = c_n x_k^n + c_{n-1} x_k^{n-1} + \cdots + c_2 x_k^2 + c_1 x_k + c_0$$

for all values of k . These m linear equations yield the linear system

$$Ax = \begin{bmatrix} x_1^n & x_1^{n-1} & \cdots & x_1^2 & x_1 & 1 \\ x_2^n & x_2^{n-1} & \cdots & x_2^2 & x_2 & 1 \\ x_3^n & x_3^{n-1} & \cdots & x_3^2 & x_3 & 1 \\ \vdots & \vdots & & \vdots & \vdots & \vdots \\ x_m^n & x_m^{n-1} & \cdots & x_m^2 & x_m & 1 \end{bmatrix} \begin{bmatrix} c_n \\ c_{n-1} \\ \vdots \\ c_2 \\ c_1 \\ c_0 \end{bmatrix} = \begin{bmatrix} y_1 \\ y_2 \\ y_3 \\ \vdots \\ y_m \end{bmatrix} = b. \quad (5.3)$$

If $m > n+1$ this system is overdetermined, requiring a least squares solution.

Working with Polynomials in NumPy

The $m \times (n+1)$ matrix A of (5.3) is called a *Vandermonde matrix*.² NumPy's `np.vander()` is a convenient tool for quickly constructing a Vandermonde matrix, given the values $\{x_k\}_{k=1}^m$ and the number of desired columns.

```
>>> print(np.vander([2, 3, 5], 2))
[[2 1]                                     # [[2**1, 2**0]
 [3 1]                                     # [3**1, 3**0]
 [5 1]]                                    # [5**1, 5**0]]

>>> print(np.vander([2, 3, 5, 4], 3))
[[ 4  2  1]                                # [[2**2, 2**1, 2**0]
 [ 9  3  1]                                # [3**2, 3**1, 3**0]
 [25  5  1]                                # [5**2, 5**1, 5**0]
 [16  4  1]]                               # [4**2, 4**1, 4**0]
```

NumPy also has powerful tools for working efficiently with polynomials. The class `np.poly1d` represents a 1-dimensional polynomial. Instances of this class are callable like a function.³ The constructor accepts the polynomial's coefficients, from largest degree to smallest.

Table 5.1 lists some attributes and methods of the `np.poly1d` class.

²Vandermonde matrices have many special properties and are useful for many applications, including polynomial interpolation and discrete Fourier analysis.

³Class instances can be made callable by implementing the `__call__()` magic method.

Attribute	Description
<code>coeffs</code>	The $n + 1$ coefficients, from greatest degree to least.
<code>order</code>	The polynomial degree (n).
<code>roots</code>	The n roots of the polynomial.
Method	Returns
<code>deriv()</code>	The coefficients of the polynomial after being differentiated.
<code>integ()</code>	The coefficients of the polynomial after being integrated (with $c_0 = 0$).

Table 5.1: Attributes and methods of the `np.poly1d` class.

```
# Create a callable object for the polynomial f(x) = (x-1)(x-2) = x^2 - 3x + 2.
>>> f = np.poly1d([1, -3, 2])
>>> print(f)
      2
1 x - 3 x + 2

# Evaluate f(x) for several values of x in a single function call.
>>> f([1, 2, 3, 4])
array([0, 0, 2, 6])
```

Problem 3. The data in `housing.npy` is nonlinear, and might be better fit by a polynomial than a line.

Write a function that uses (5.3) to calculate the polynomials of degree 3, 6, 9, and 12 that best fit the data. Plot the original data points and each least squares polynomial together in individual subplots.

(Hint: define a separate, refined domain with `np.linspace()` and use this domain to smoothly plot the polynomials.)

Instead of using Problem 1 to solve the normal equations, you may use SciPy's least squares routine, `scipy.linalg.lstsq()`.

```
>>> from scipy import linalg as la

# Define A and b appropriately.

# Solve the normal equations using SciPy's least squares routine.
# The least squares solution is the first of four return values.
>>> x = la.lstsq(A, b)[0]
```

Compare your results to `np.polyfit()`. This function receives an array of x values, an array of y values, and an integer for the polynomial degree, and returns the coefficients of the best fit polynomial of that degree.

ACHTUNG!

Having more parameters in a least squares model is not always better. For a set of m points, the best fit polynomial of degree $m - 1$ *interpolates* the data set, meaning that $p(x_k) = y_k$ exactly for each k . In this case there are enough unknowns that the system is no longer overdetermined. However, such polynomials are highly subject to numerical errors and are unlikely to accurately represent true patterns in the data.

Choosing to have too many unknowns in a fitting problem is (fittingly) called *overfitting*, and is an important issue to avoid in any statistical model.

Fitting a Circle

Suppose the set of m points $\{(x_k, y_k)\}_{k=1}^m$ are arranged in a nearly circular pattern. The general equation of a circle with radius r and center (c_1, c_2) is

$$(x - c_1)^2 + (y - c_2)^2 = r^2. \quad (5.4)$$

The circle is uniquely determined by r , c_1 , and c_2 , so these are the parameters that should be solved for in a least squares formulation of the problem. However, (5.4) is not linear in any of these variables.

$$\begin{aligned} (x - c_1)^2 + (y - c_2)^2 &= r^2 \\ x^2 - 2c_1x + c_1^2 + y^2 - 2c_2y + c_2^2 &= r^2 \\ x^2 + y^2 &= 2c_1x + 2c_2y + r^2 - c_1^2 - c_2^2 \end{aligned} \quad (5.5)$$

The quadratic terms x^2 and y^2 are acceptable because the points $\{(x_k, y_k)\}_{k=1}^m$ are given. To eliminate the nonlinear terms in the unknown parameters r , c_1 , and c_2 , define a new variable $c_3 = r^2 - c_1^2 - c_2^2$. Then for each point (x_k, y_k) , (5.5) becomes

$$2c_1x_k + 2c_2y_k + c_3 = x_k^2 + y_k^2.$$

These m equations are linear in c_1 , c_2 , and c_3 , and can be written as the linear system

$$\begin{bmatrix} 2x_1 & 2y_1 & 1 \\ 2x_2 & 2y_2 & 1 \\ \vdots & \vdots & \vdots \\ 2x_m & 2y_m & 1 \end{bmatrix} \begin{bmatrix} c_1 \\ c_2 \\ c_3 \end{bmatrix} = \begin{bmatrix} x_1^2 + y_1^2 \\ x_2^2 + y_2^2 \\ \vdots \\ x_m^2 + y_m^2 \end{bmatrix}. \quad (5.6)$$

After solving for the least squares solution, r can be recovered with the relation $r = \sqrt{c_1^2 + c_2^2 + c_3}$. Finally, plotting a circle is best done with polar coordinates. Using the same variables as before, the circle can be represented in polar coordinates by setting

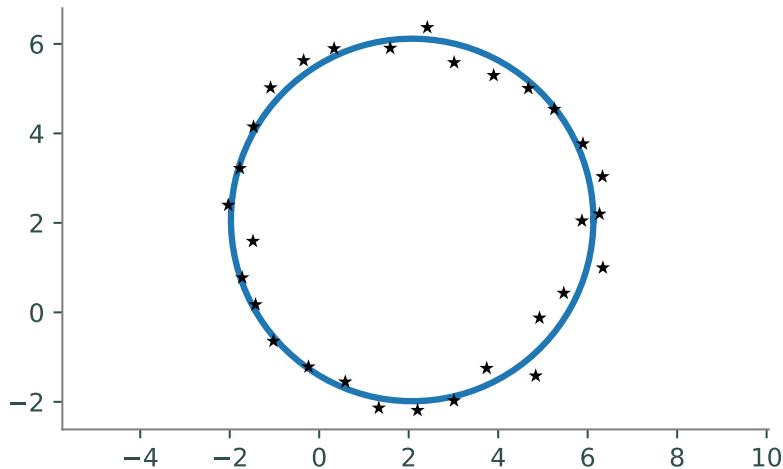

$$x = r \cos(\theta) + c_1, \quad y = r \sin(\theta) + c_2, \quad \theta \in [0, 2\pi]. \quad (5.7)$$

To plot the circle, solve the least squares system for c_1 , c_2 , and r , define an array for θ , then use (5.7) to calculate the coordinates of the points the circle.

```
# Load some data and construct the matrix A and the vector b.
>>> xk, yk = np.load("circle.npy").T
>>> A = np.column_stack((2*xk, 2*yk, np.ones_like(xk)))
>>> b = xk**2 + yk**2

# Calculate the least squares solution and solve for the radius.
>>> c1, c2, c3 = la.lstsq(A, b)[0]
>>> r = np.sqrt(c1**2 + c2**2 + c3)

# Plot the circle using polar coordinates.
>>> theta = np.linspace(0, 2*np.pi, 200)
>>> x = r*np.cos(theta) + c1
>>> y = r*np.sin(theta) + c2
>>> plt.plot(x, y) # Plot the circle.
>>> plt.plot(xk, yk, 'k*') # Plot the data points.
>>> plt.axis("equal")
```

Problem 4. The general equation for an ellipse is

$$ax^2 + bx + cxy + dy + ey^2 = 1.$$

Write a function that calculates the parameters for the ellipse that best fits the data in the file `ellipse.npy`. Plot the original data points and the ellipse together, using the following function to plot the ellipse.

```
def plot_ellipse(a, b, c, d, e):
    """Plot an ellipse of the form ax^2 + bx + cxy + dy + ey^2 = 1."""
    theta = np.linspace(0, 2*np.pi, 200)
    cos_t, sin_t = np.cos(theta), np.sin(theta)
```

```

A = a*(cos_t**2) + c*cos_t*sin_t + e*(sin_t**2)
B = b*cos_t + d*sin_t
r = (-B + np.sqrt(B**2 + 4*A)) / (2*A)
plt.plot(r*cos_t, r*sin_t, lw=2)
plt.gca().set_aspect("equal", "datalim")

```

Computing Eigenvalues

The eigenvalues of an $n \times n$ matrix A are the roots of its characteristic polynomial $\det(A - \lambda I)$. Thus, finding the eigenvalues of A amounts to computing the roots of a polynomial of degree n . However, for $n \geq 5$, it is provably impossible to find an algebraic closed-form solution to this problem.⁴ In addition, numerically computing the roots of a polynomial is a famously ill-conditioned problem, meaning that small changes in the coefficients of the polynomial (brought about by small changes in the entries of A) may yield wildly different results. Instead, eigenvalues must be computed with iterative methods.

The Power Method

The *dominant eigenvalue* of the $n \times n$ matrix A is the unique eigenvalue of greatest magnitude, if such an eigenvalue exists. The *power method* iteratively computes the dominant eigenvalue of A and its corresponding eigenvector.

Begin by choosing a vector \mathbf{x}_0 such that $\|\mathbf{x}_0\|_2 = 1$, and define

$$\mathbf{x}_{k+1} = \frac{A\mathbf{x}_k}{\|A\mathbf{x}_k\|_2}.$$

If A has a dominant eigenvalue λ , and if the projection of \mathbf{x}_0 onto the subspace spanned by the eigenvectors corresponding to λ is nonzero, then the sequence of vectors $(\mathbf{x}_k)_{k=0}^{\infty}$ converges to an eigenvector \mathbf{x} of A corresponding to λ .

Since \mathbf{x} is an eigenvector of A , $A\mathbf{x} = \lambda\mathbf{x}$. Left multiplying by \mathbf{x}^T on each side results in $\mathbf{x}^T A \mathbf{x} = \lambda \mathbf{x}^T \mathbf{x}$, and hence $\lambda = \frac{\mathbf{x}^T A \mathbf{x}}{\mathbf{x}^T \mathbf{x}}$. This ratio is called the *Rayleigh quotient*. However, since each \mathbf{x}_k is normalized, $\mathbf{x}^T \mathbf{x} = \|\mathbf{x}\|_2^2 = 1$, so $\lambda = \mathbf{x}^T A \mathbf{x}$.

The entire algorithm is summarized below.

Algorithm 1

```

1: procedure POWERMETHOD( $A$ )
2:    $m, n \leftarrow \text{shape}(A)$                                       $\triangleright A$  is square so  $m = n$ .
3:    $\mathbf{x}_0 \leftarrow \text{random}(n)$                                  $\triangleright$  A random vector of length  $n$ 
4:    $\mathbf{x}_0 \leftarrow \mathbf{x}_0 / \|\mathbf{x}_0\|_2$                           $\triangleright$  Normalize  $\mathbf{x}_0$ 
5:   for  $k = 0, 1, \dots, N - 1$  do
6:      $\mathbf{x}_{k+1} \leftarrow A\mathbf{x}_k$ 
7:      $\mathbf{x}_{k+1} \leftarrow \mathbf{x}_{k+1} / \|\mathbf{x}_{k+1}\|_2$ 
8:   return  $\mathbf{x}_N^T A \mathbf{x}_N, \mathbf{x}_N$ 

```

⁴This result, called *Abel's impossibility theorem*, was first proven by Niels Heinrik Abel in 1824.

The power method is limited by a few assumptions. First, not all square matrices A have a dominant eigenvalue. However, the Perron-Frobenius theorem guarantees that if all entries of A are positive, then A has a dominant eigenvalue. Second, there is no way to choose an \mathbf{x}_0 that is guaranteed to have a nonzero projection onto the span of the eigenvectors corresponding to λ , though a random \mathbf{x}_0 will almost surely satisfy this condition. Even with these assumptions, a rigorous proof that the power method converges is most convenient with tools from spectral calculus, and as such will not be pursued here.

Problem 5. Write a function that accepts an $n \times n$ matrix A , a maximum number of iterations N , and a stopping tolerance tol . Use Algorithm 1 to compute the dominant eigenvalue of A and a corresponding eigenvector. Continue the loop in step 5 until either $\|\mathbf{x}_{k+1} - \mathbf{x}_k\|_2$ is less than the tolerance tol , or until iterating the maximum number of times N .

Test your function on square matrices with all positive entries, verifying that $A\mathbf{x} = \lambda\mathbf{x}$. Use SciPy's eigenvalue solver, `scipy.linalg.eig()`, to compute all of the eigenvalues and corresponding eigenvectors of A and check that λ is the dominant eigenvalue of A . There is also a file called `test_lstsq_eigs.py` that has prewritten unit tests for this problem that you can use to check your code.

```
# Construct a random matrix with positive entries.
>>> A = np.random.random((10, 10))

# Compute the eigenvalues and eigenvectors of A via SciPy.
>>> eigs, vecs = la.eig(A)

# Get the dominant eigenvalue and eigenvector of A.
# The eigenvector of the kth eigenvalue is the kth column of 'vecs'.
>>> loc = np.argmax(eigs)
>>> lamb, x = eigs[loc], vecs[:, loc]

# Verify that Ax = lambda x.
>>> np.allclose(A @ x, lamb * x)
True
```

The QR Algorithm

An obvious shortcoming of the power method is that it only computes one eigenvalue and eigenvector. The QR algorithm, on the other hand, attempts to find all eigenvalues of A .

Let $A_0 = A$, and for arbitrary k let $Q_k R_k = A_k$ be the QR decomposition of A_k . Since A is square, so are Q_k and R_k , so they can be recombined in reverse order:

$$A_{k+1} = R_k Q_k.$$

This recursive definition establishes an important relation between the A_k :

$$Q_k^{-1} A_k Q_k = Q_k^{-1} (Q_k R_k) Q_k = (Q_k^{-1} Q_k)(R_k Q_k) = R_k.$$

Thus, A_k is orthonormally similar to A_{k+1} , and similar matrices have the same eigenvalues. The series of matrices $(A_k)_{k=0}^{\infty}$ converges to the block matrix

$$S = \begin{bmatrix} S_1 & * & \cdots & * \\ \mathbf{0} & S_2 & \ddots & \vdots \\ \vdots & \ddots & \ddots & * \\ \mathbf{0} & \cdots & \mathbf{0} & S_m \end{bmatrix}. \quad \text{For example, } S = \begin{bmatrix} s_1 & * & * & \cdots & * \\ 0 & s_{2,1} & s_{2,2} & \cdots & * \\ & s_{2,3} & s_{2,4} & \cdots & * \\ & & & \ddots & \vdots \\ & & & & s_m \end{bmatrix}.$$

Each S_i is either a 1×1 or 2×2 matrix.⁵ In the example above on the right, since the first subdiagonal entry is zero, S_1 is the 1×1 matrix with a single entry, s_1 . But as $s_{2,3}$ is not zero, S_2 is 2×2 .

Since S is block upper triangular, its eigenvalues are the eigenvalues of its diagonal S_i blocks. Then because A is similar to each A_k , those eigenvalues of S are the eigenvalues of A .

When A has real entries but complex eigenvalues, 2×2 S_i blocks appear in S . Finding eigenvalues of a 2×2 matrix is equivalent to finding the roots of a 2nd degree polynomial,

$$\det(S_i - \lambda I) = \begin{vmatrix} a - \lambda & b \\ c & d - \lambda \end{vmatrix} = (a - \lambda)(d - \lambda) - bc = \lambda^2 - (a + d)\lambda + (ad - bc), \quad (5.8)$$

which has a closed form solution via the quadratic equation. This also demonstrates that complex eigenvalues come in conjugate pairs.

Hessenberg Preconditioning

A matrix in *upper Hessenberg form* is one that has all entries below the first subdiagonal equal to zero. This is similar to an upper triangular matrix, except that the entries directly below the diagonal are also allowed to be nonzero. The QR algorithm works more accurately and efficiently on matrices that are in upper Hessenberg form, as upper Hessenberg matrices are already close to triangular. Furthermore, if $H = QR$ is the QR decomposition of upper Hessenberg H then RQ is also upper Hessenberg, so the almost-triangular form is preserved at each iteration. Putting a matrix in upper Hessenberg form before applying the QR algorithm is called *Hessenberg preconditioning*.

With preconditioning in mind, the entire QR algorithm is as follows.

⁵If all of the S_i are 1×1 matrices, then the upper triangular S is called the *Schur form* of A . If some of the S_i are 2×2 matrices, then S is called the *real Schur form* of A .

Algorithm 2

```

1: procedure QR_ALGORITHM( $A, N$ )
2:    $m, n \leftarrow \text{shape}(A)$ 
3:    $S \leftarrow \text{hessenberg}(A)$                                  $\triangleright$  Put  $A$  in upper Hessenberg form.
4:   for  $k = 0, 1, \dots, N - 1$  do
5:      $Q, R \leftarrow S$                                           $\triangleright$  Get the QR decomposition of  $A_k$ .
6:      $S \leftarrow RQ$                                           $\triangleright$  Recombine  $R_k$  and  $Q_k$  into  $A_{k+1}$ .
7:     eigs  $\leftarrow []$                                       $\triangleright$  Initialize an empty list of eigenvalues.
8:      $i \leftarrow 0$ 
9:     while  $i < n$  do
10:       if  $S_i$  is  $1 \times 1$  then
11:         Append the only entry  $s_i$  of  $S_i$  to eigs
12:       else if  $S_i$  is  $2 \times 2$  then
13:         Calculate the eigenvalues of  $S_i$ 
14:         Append the eigenvalues of  $S_i$  to eigs
15:          $i \leftarrow i + 1$ 
16:        $i \leftarrow i + 1$                                           $\triangleright$  Move to the next  $S_i$ .
17:   return eigs

```

Problem 6. Write a function that accepts an $n \times n$ matrix A , a number of iterations N , and a tolerance tol . Use Algorithm 2 to implement the QR algorithm with Hessenberg preconditioning, returning the eigenvalues of A .

Consider the following implementation details.

- Use `scipy.linalg.hessenberg()` or your own Hessenburg algorithm to reduce A to upper Hessenberg form in step 3.
- The loop in step 4 should run for N total iterations.
- Use `scipy.linalg.qr()` or one of your own QR factorization routines to compute the QR decomposition of S in step 5. Note that since S is in upper Hessenberg form, Givens rotations are the most efficient way to produce Q and R .
- Assume that S_i is 1×1 in step 10 if one of two following criteria hold:
 - S_i is the last diagonal entry of S .
 - The absolute value of element below the i th main diagonal entry of S (the lower left element of the 2×2 block) is less than tol .
- If S_i is 2×2 , use the quadratic formula and (5.8) to compute its eigenvalues. Use the function `cmath.sqrt()` to correctly compute the square root of a negative number.

Test your function on small random symmetric matrices, comparing your results to SciPy's `scipy.linalg.eig()`. While the QR algorithm works on arbitrary matrices, it has better convergence properties for symmetric matrices, which makes them better for testing. To construct a random symmetric matrix, note that $A + A^T$ is always symmetric.

UNIT TEST

There is a file called `test_lstsq_eigs.py` that contains some prewritten unit tests for Problem 5. There is a place for you to add your own unit tests for Problem 6 called `test_qr_algorithm`. You are required to include at least one unit test which will be graded.

NOTE

Algorithm 2 is theoretically sound, but can still be greatly improved. Most modern computer packages instead use the *implicit QR algorithm*, an improved version of the QR algorithm, to compute eigenvalues.

For large matrices, there are other iterative methods besides the power method and the QR algorithm for efficiently computing eigenvalues. They include the Arnoldi iteration, the Jacobi method, the Rayleigh quotient method, and others.

Additional Material

Variations on the Linear Least Squares Problem

If W is an $n \times n$ is symmetric positive-definite matrix, then the function $\|\cdot\|_{W^2} : \mathbb{R}^n \rightarrow \mathbb{R}$ given by

$$\|\mathbf{x}\|_{W^2} = \|W\mathbf{x}\|_2 = \sqrt{\mathbf{x}^\top W^\top W \mathbf{x}}$$

defines a norm and is called a *weighted 2-norm*. Given the overdetermined system $A\mathbf{x} = \mathbf{b}$, the problem of choosing $\hat{\mathbf{x}}$ to minimize $\|A\hat{\mathbf{x}} - \mathbf{b}\|_{W^2}$ is called a *weighted least squares* (WLS) problem. This problem has a slightly different set of normal equations,

$$A^\top W^\top W A \hat{\mathbf{x}} = A^\top W^\top W \mathbf{b}.$$

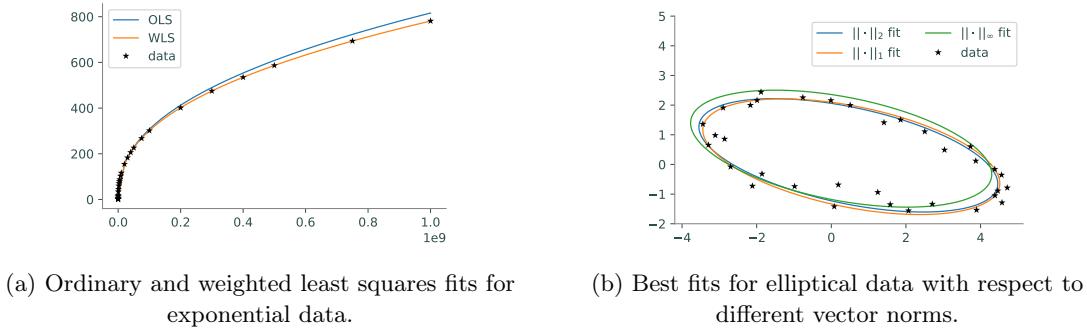

However, letting $C = WA$ and $\mathbf{z} = W\mathbf{b}$, this equation reduces to the usual normal equations,

$$C^\top C \hat{\mathbf{x}} = C^\top \mathbf{z},$$

so a WLS problem can be solved in the same way as an ordinary least squares (OLS) problem.

Weighted least squares is useful when some points in a data set are more important than others. Typically W is chosen to be a diagonal matrix, and each positive diagonal entry $W_{i,i}$ indicate how much weight should be given to the i th data point. For example, Figure 5.2a shows OLS and WLS fits of an exponential curve $y = ae^{kx}$ to data that gets more sparse as x increases, where the matrix W is chosen to give more weight to the data with larger x values.

Alternatively, the least squares problem can be formulated with other common vector norms, but such problems cannot be solved via the normal equations. For example, minimizing $\|A\mathbf{x} - \mathbf{b}\|_1$ or $\|A\mathbf{x} - \mathbf{b}\|_\infty$ is usually done by solving an equivalent *linear program*, a type of constrained optimization problem. These norms may be better suited to a particular application than the regular 2-norm. Figure 5.2b illustrates how different norms give slightly different results in the context of Problem 4.

(a) Ordinary and weighted least squares fits for exponential data.

(b) Best fits for elliptical data with respect to different vector norms.

Figure 5.2: Variations on the ordinary least squares problem.

The Inverse Power Method

The major drawback of the power method is that it only computes a single eigenvector-eigenvalue pair, and it is always the eigenvalue of largest magnitude. The *inverse power method*, sometimes simply called the *inverse iteration*, is a way of computing an eigenvalue that is closest in magnitude to an initial guess. The key observation is that if λ is an eigenvalue of A , then $1/(\lambda - \mu)$ is an eigenvalue of $(A - \mu I)^{-1}$, so applying the power method to $(A - \mu I)^{-1}$ yields the eigenvalue of A that is closest in magnitude to μ .

The inverse power method is more expensive than the regular power method because at each iteration, instead of a matrix-vector multiplication (step 6 of Algorithm 1), a system of the form $(A - \mu I)\mathbf{x} = \mathbf{b}$ must be solved. To speed this step up, start by taking the LU or QR factorization of $A - \mu I$ before the loop, then use the factorization and back substitution to solve the system quickly within the loop. For instance, if $QR = A - \mu I$, then since $Q^{-1} = Q^T$,

$$\mathbf{b} = (A - \mu I)\mathbf{x} = QR\mathbf{x} \Leftrightarrow R\mathbf{x} = Q^T\mathbf{b},$$

which is a triangular system. This version of the algorithm is described below.

Algorithm 3

```

1: procedure INVERSEPOWERMETHOD( $A, \mu$ )
2:    $m, n \leftarrow \text{shape}(A)$ 
3:    $\mathbf{x}_0 \leftarrow \text{random}(n)$ 
4:    $\mathbf{x}_0 \leftarrow \mathbf{x}_0 / \|\mathbf{x}_0\|$ 
5:    $Q, R \leftarrow A - \mu I$                                  $\triangleright$  Factor  $A - \mu I$  with la.qr().
6:   for  $k = 0, 1, 2, \dots, N - 1$  do
7:     Solve  $R\mathbf{x}_{k+1} = Q^T\mathbf{x}_k$                        $\triangleright$  Use la.solve_triangular().
8:      $\mathbf{x}_{k+1} \leftarrow \mathbf{x}_{k+1} / \|\mathbf{x}_{k+1}\|$ 
9:   return  $\mathbf{x}_N^T A \mathbf{x}_N, \mathbf{x}_N$ 

```

It is worth noting that the QR algorithm can be improved with a similar technique: instead of computing the QR factorization of A_k , factor the shifted matrix $A_k - \mu_k I$, where μ_k is a guess for an eigenvalue of A , and unshift the recombined factorization accordingly. That is, compute

$$\begin{aligned} Q_k R_k &= A_k - \mu_k I, \\ A_{k+1} &= R_k Q_k + \mu_k I. \end{aligned}$$

This technique yields the *single-shift QR algorithm*. Another variant, the *practical QR algorithm*, uses intelligent shifts and recursively operates on smaller blocks of A_{k+1} where possible. See [QSS10, TB97] for further discussion.

6

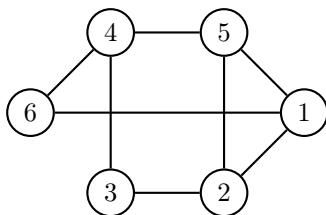

Image Segmentation

Lab Objective: *Graph theory has a variety of applications. A graph (or network) can be represented in many ways on a computer. In this lab we study a common matrix representation for graphs and show how certain properties of the matrix representation correspond to inherent properties of the original graph. We also introduce tools for working with images in Python, and conclude with an application of using graphs and linear algebra to segment images.*

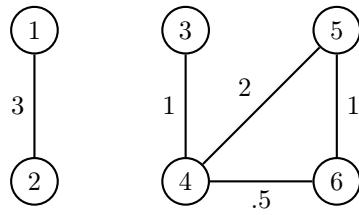

Graphs as Matrices

A *graph* is a mathematical structure that represents relationships between objects. Graphs are defined by $G = (V, E)$, where V is a set of *vertices* (or *nodes*) and E is a set of *edges*, each of which connects one node to another. A graph can be classified in several ways.

- The edges of an *undirected* graph are bidirectional: if an edge goes from node A to node B , then that same edge also goes from B to A . For example, the graphs G_1 and G_2 in Figure 6.1 are both undirected. In a *directed graph*, edges only go one way, usually indicated by an arrow pointing from one node to another. In this lab, we focus on undirected graphs.
- The edges of a *weighted* graph have a weight assigned to them, such as G_2 . A weighted graph could represent a collection of cities with roads connecting them: each vertex would represent a city, and the edges would represent roads between the cities. The length of each road could be the weight of the corresponding edge. An *unweighted* graph like G_1 does not have weights assigned to its edges, but any unweighted graph can be thought of as a weighted graph by assigning a weight of 1 to every edge.

(a) G_1 , an unweighted undirected graph.

(b) G_2 , a weighted undirected graph.

Figure 6.1

Adjacency, Degree, and Laplacian Matrices

For computation and analysis, graphs are commonly represented by a few special matrices. For these definitions, let G be a graph with N nodes and let w_{ij} be the weight of the edge connecting node i to node j (if such an edge exists).

1. The *adjacency matrix* of G is the $N \times N$ matrix A with entries

$$a_{ij} = \begin{cases} w_{ij} & \text{if an edge connects node } i \text{ and node } j \\ 0 & \text{otherwise.} \end{cases}$$

The adjacency matrices A_1 of G_1 and A_2 of G_2 are

$$A_1 = \begin{bmatrix} 0 & 1 & 0 & 0 & 1 & 1 \\ 1 & 0 & 1 & 0 & 1 & 0 \\ 0 & 1 & 0 & 1 & 0 & 0 \\ 0 & 0 & 1 & 0 & 1 & 1 \\ 1 & 1 & 0 & 1 & 0 & 0 \\ 1 & 0 & 0 & 1 & 0 & 0 \end{bmatrix}, \quad A_2 = \begin{bmatrix} 0 & 3 & 0 & 0 & 0 & 0 \\ 3 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 1 & 0 & 0 \\ 0 & 0 & 1 & 0 & 2 & .5 \\ 0 & 0 & 0 & 2 & 0 & 1 \\ 0 & 0 & 0 & .5 & 1 & 0 \end{bmatrix}.$$

Notice that these adjacency matrices are symmetric. This is always the case for undirected graphs since the edges are bidirectional.

2. The *degree matrix* of G is the $N \times N$ diagonal matrix D whose i th diagonal entry is

$$d_{ii} = \sum_{j=1}^N w_{ij}. \quad (6.1)$$

The degree matrices D_1 of G_1 and D_2 of G_2 are

$$D_1 = \begin{bmatrix} 3 & 0 & 0 & 0 & 0 & 0 \\ 0 & 3 & 0 & 0 & 0 & 0 \\ 0 & 0 & 2 & 0 & 0 & 0 \\ 0 & 0 & 0 & 3 & 0 & 0 \\ 0 & 0 & 0 & 0 & 3 & 0 \\ 0 & 0 & 0 & 0 & 0 & 2 \end{bmatrix}, \quad D_2 = \begin{bmatrix} 3 & 0 & 0 & 0 & 0 & 0 \\ 0 & 3 & 0 & 0 & 0 & 0 \\ 0 & 0 & 1 & 0 & 0 & 0 \\ 0 & 0 & 0 & 3.5 & 0 & 0 \\ 0 & 0 & 0 & 0 & 3 & 0 \\ 0 & 0 & 0 & 0 & 0 & 1.5 \end{bmatrix}.$$

The i th diagonal entry of D is called the *degree* of node i , the sum of the weights of the edges leaving node i .

3. The *Laplacian matrix* of G is the $N \times N$ matrix L defined as

$$L = D - A, \quad (6.2)$$

where D is the degree matrix of G and A is the adjacency matrix of G . For G_1 and G_2 , the Laplacian matrices L_1 and L_2 are

$$L_1 = \begin{bmatrix} 3 & -1 & 0 & 0 & -1 & -1 \\ -1 & 3 & -1 & 0 & -1 & 0 \\ 0 & -1 & 2 & -1 & 0 & 0 \\ 0 & 0 & -1 & 3 & -1 & -1 \\ -1 & -1 & 0 & -1 & 3 & 0 \\ -1 & 0 & 0 & -1 & 0 & 2 \end{bmatrix}, \quad L_2 = \begin{bmatrix} 3 & -3 & 0 & 0 & 0 & 0 \\ -3 & 3 & 0 & 0 & 0 & 0 \\ 0 & 0 & 1 & -1 & 0 & 0 \\ 0 & 0 & -1 & 3.5 & -2 & -.5 \\ 0 & 0 & 0 & -2 & 3 & -1 \\ 0 & 0 & 0 & -.5 & -1 & 1.5 \end{bmatrix}.$$

Problem 1. Write a function that accepts the adjacency matrix A of a graph G . Use (6.1) and (6.2) to compute the Laplacian matrix L of G .

(Hint: The diagonal entries of D can be computed in one line by summing A over an axis.)

Test your function on the graphs G_1 and G_2 from Figure 6.1 and validate your results with `scipy.sparse.csgraph.laplacian()`.

Connectivity

A *connected graph* is a graph where every vertex is connected to every other vertex by at least one path. For example, G_1 is connected, whereas G_2 is not because there is no path from node 1 (or node 2) to node 3 (or nodes 4, 5, or 6). The naïve brute-force algorithm for determining if a graph is connected is to check that there is a path from each edge to every other edge. While this may work for very small graphs, most interesting graphs have thousands of vertices, and for such graphs this approach is prohibitively expensive. Luckily, an interesting result from algebraic graph theory relates the connectivity of a graph to its Laplacian matrix.

If L is the Laplacian matrix of a graph, then the definition of D and the construction $L = D - A$ guarantees that the rows (and columns) of L must each sum to 0. Therefore L cannot have full rank, so $\lambda = 0$ must be an eigenvalue of L . Furthermore, if L represents a graph that is **not** connected, more than one of the eigenvalues of L must be zero. To see this, let $J \subset \{1, 2, \dots, N\}$ such that the vertices $\{v_j\}_{j \in J}$ form a connected component of the graph, meaning that there is a path between each pair of vertices in the set. Next, let \mathbf{x} be the vector with entries

$$x_k = \begin{cases} 1, & k \in J \\ 0, & k \notin J. \end{cases}$$

Then \mathbf{x} is an eigenvector of L corresponding to the eigenvalue $\lambda = 0$.

For example, the example graph G_2 has two connected components.

1. $J_1 = \{1, 2\}$ so that $\mathbf{x}_1 = [1, 1, 0, 0, 0, 0]^T$. Then

$$L_2 \mathbf{x}_1 = \begin{bmatrix} 3 & -3 & 0 & 0 & 0 & 0 \\ -3 & 3 & 0 & 0 & 0 & 0 \\ 0 & 0 & 1 & -1 & 0 & 0 \\ 0 & 0 & -1 & 3.5 & -2 & -.5 \\ 0 & 0 & 0 & -2 & 3 & -1 \\ 0 & 0 & 0 & -.5 & -1 & 1.5 \end{bmatrix} \begin{bmatrix} 1 \\ 1 \\ 0 \\ 0 \\ 0 \\ 0 \end{bmatrix} = \begin{bmatrix} 0 \\ 0 \\ 0 \\ 0 \\ 0 \\ 0 \end{bmatrix} = \mathbf{0}.$$

2. $J_2 = \{3, 4, 5, 6\}$ and hence $\mathbf{x}_2 = [0, 0, 1, 1, 1, 1]^T$. Then

$$L_2 \mathbf{x}_2 = \begin{bmatrix} 3 & -3 & 0 & 0 & 0 & 0 \\ -3 & 3 & 0 & 0 & 0 & 0 \\ 0 & 0 & 1 & -1 & 0 & 0 \\ 0 & 0 & -1 & 3.5 & -2 & -.5 \\ 0 & 0 & 0 & -2 & 3 & -1 \\ 0 & 0 & 0 & -.5 & -1 & 1.5 \end{bmatrix} \begin{bmatrix} 0 \\ 0 \\ 1 \\ 1 \\ 1 \\ 1 \end{bmatrix} = \begin{bmatrix} 0 \\ 0 \\ 0 \\ 0 \\ 0 \\ 0 \end{bmatrix} = \mathbf{0}.$$

In fact, it can be shown that the number of zero eigenvalues of the Laplacian exactly equals the number of connected components. This makes calculating how many connected components are in a graph only as hard as calculating the eigenvalues of its Laplacian.

A Laplacian matrix L is always a positive semi-definite matrix when all weights in the graph are positive, meaning that its eigenvalues are each nonnegative. The second smallest eigenvalue of L is called the *algebraic connectivity* of the graph. It is clearly 0 for non-connected graphs, but for a connected graph, the algebraic connectivity provides useful information about its sparsity or “connectedness.” A higher algebraic connectivity indicates that the graph is more strongly connected.

Problem 2. Write a function that accepts the adjacency matrix A of a graph G and a small tolerance value `tol`. Compute the number of connected components in G and its algebraic connectivity. Consider all eigenvalues that are less than the given `tol` to be zero.

Use `scipy.linalg.eig()` or `scipy.linalg.eigvals()` to compute the eigenvalues of the Laplacian matrix. These functions return complex eigenvalues (with negligible imaginary parts); use `np.real()` to extract the real parts.

UNIT TEST

Write unit tests for Problem 2 in `test_image_segmentation.py`. There are example unit tests for Problem 1 to help check the Laplacian.

Images as Matrices

Computer images are stored as arrays of integers that indicate pixel values. Most $m \times n$ grayscale (black and white) images are stored in Python as a $m \times n$ NumPy arrays, while most $m \times n$ color images are stored as 3-dimensional $m \times n \times 3$ arrays. Color image arrays can be thought of as a stack of three $m \times n$ arrays, one each for red, green, and blue values. The datatype for an image array is `np.uint8`, unsigned 8-bit integers that range from 0 to 255. A 0 indicates a black pixel while a 255 indicates a white pixel.

Use `imageio.v3.imread()` to read an image from a file and `imageio.v3.imwrite()` to save an image. Matplotlib’s `plt.imshow()` displays an image array, but it displays arrays of floats between 0 and 1 more cleanly than arrays of 8-bit integers. Therefore it is customary to scale the array by dividing each entry by 255 before processing or showing the image. In this case, a 0 still indicates a black pixel, but now a 1 indicates pure white.

```
>>> from imageio.v3 import imread
>>> from matplotlib import pyplot as plt

>>> image = imread("dream.png")      # Read a (very) small image.
>>> print(image.shape)            # Since the array is 3-dimensional,
(48, 48, 3)                      # this is a color image.

# The image is read in as integers from 0 to 255.
>>> print(image.min(), image.max(), image.dtype)
0 254 uint8

# Scale the image to floats between 0 and 1 for Matplotlib.
>>> scaled = image / 255.
```

```
>>> print(scaled.min(), scaled.max(), scaled.dtype)
0.0 0.996078431373 float64

# Display the scaled image.
>>> plt.imshow(scaled)
>>> plt.axis("off")
```

A color image can be converted to grayscale by averaging the RGB values of each pixel, resulting in a 2-D array called the *brightness* of the image. To properly display a grayscale image, specify the keyword argument `cmap="gray"` in `plt.imshow()`.

```
# Average the RGB values of a colored image to obtain a grayscale image.
>>> brightness = scaled.mean(axis=2)          # Average over the last axis.
>>> print(brightness.shape)                  # Note that the array is now 2-D.
(48, 48)

# Display the image in gray.
>>> plt.imshow(brightness, cmap="gray")
>>> plt.axis("off")
```

Finally, it is often important in applications to flatten an image matrix into a large 1-D array. Use `np.ravel()` to convert a $m \times n$ array into a 1-D array with mn entries.

```
>>> import numpy as np
>>> A = np.random.randint(0, 10, (3, 4))
>>> print(A)
[[4 4 7 7]
 [8 1 2 0]
 [7 0 0 9]]

# Unravel the 2-D array (by rows) into a 1-D array.
>>> np.ravel(A)
array([4, 4, 7, 7, 8, 1, 2, 0, 7, 0, 0, 9])

# Unravel a grayscale image into a 1-D array and check its size.
>>> M,N = brightness.shape
>>> flat_brightness = np.ravel(brightness)
>>> M*N == flat_brightness.size
True
>>> print(flat_brightness.shape)
(2304,)
```

Problem 3. Define a class called `ImageSegmenter`.

1. Write the constructor so that it accepts the name of an image file. Read the image, scale it so that it contains floats between 0 and 1, then store it as an attribute. If the image is in color, compute its brightness matrix by averaging the RGB values at each pixel (if it is a grayscale image, the image array itself is the brightness matrix). Flatten the brightness matrix into a 1-D array and store it as an attribute.
2. Write a method called `show_original()` that displays the original image. If the original image is grayscale, remember to use `cmap="gray"` as part of `plt.imshow()`.

ACHTUNG!

Matplotlib's `plt.imread()` also reads image files. However, this function automatically scales PNG image entries to floats between 0 and 1, but it still reads non-PNG image entries as 8-bit integers. To avoid this inconsistent behavior, always use `imageio.v3.imread()` to read images and divide by 255 when scaling is desired.

Graph-based Image Segmentation

Image segmentation is the process of finding natural boundaries in an image and partitioning the image along those boundaries (see Figure 6.2). Though humans can easily pick out portions of an image that “belong together,” it takes quite a bit of work to teach a computer to recognize boundaries and sections in an image. However, segmenting an image often makes it easier to analyze, so image segmentation is ongoing area of research in computer vision and image processing.

Figure 6.2: The image `dream.png` and its segments.

There are many ways to approach image segmentation. The following algorithm, developed by Jianbo Shi and Jitendra Malik in 2000 [SM00], converts the image to a graph and “cuts” it into two connected components.

Constructing the Image Graph

Let G be a graph whose vertices are the mn pixels of an $m \times n$ image (either grayscale or color). Each vertex i has a brightness $B(i)$, the grayscale or average RGB value of the pixel, as well as a coordinate location $X(i)$, the indices of the pixel in the original image array.

Define w_{ij} , the weight of the edge between pixels i and j , by

$$w_{ij} = \begin{cases} \exp\left(-\frac{|B(i)-B(j)|}{\sigma_B^2} - \frac{\|X(i)-X(j)\|}{\sigma_X^2}\right) & \text{if } \|X(i)-X(j)\| < r \\ 0 & \text{otherwise,} \end{cases} \quad (6.3)$$

where r , σ_B^2 and σ_X^2 are constants for tuning the algorithm. In this context, $\|\cdot\|$ is the standard *euclidean norm*, meaning that $\|X(i) - X(j)\|$ is the physical distance between vertices i and j , measured in pixels.

With this definition for w_{ij} , pixels that are farther apart than the radius r are not connected at all in G . Pixels within r of each other are more strongly connected if they are similar in brightness and close together (the value in the exponential is negative but close to zero). On the other hand, highly contrasting pixels where $|B(i) - B(j)|$ is large have weaker connections (the value in the exponential is highly negative).

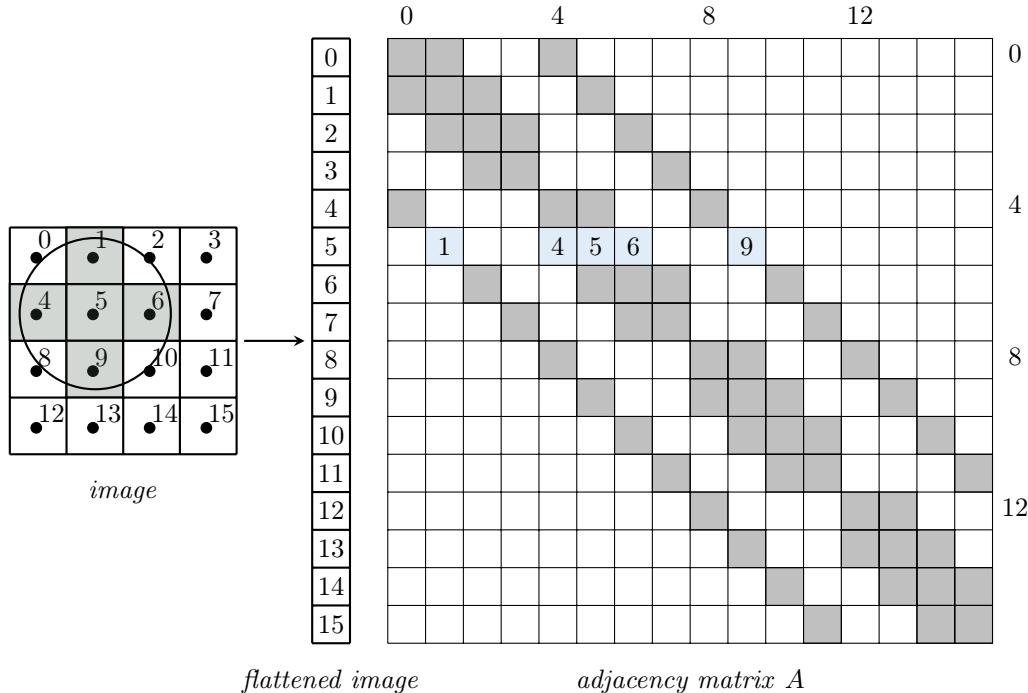

Figure 6.3: The grid on the left represents a 4×4 ($m \times n$) image with 16 pixels. On the right is the corresponding 16×16 ($mn \times mn$) adjacency matrix with all nonzero entries shaded. For example, in row 5, entries 1, 4, 5, 6, and 9 are nonzero because those pixels are within radius $r = 1.2$ of pixel 5.

Since there are mn total pixels, the adjacency matrix A of G with entries w_{ij} is $mn \times mn$. With a relatively small radius r , A is relatively sparse, and should therefore be constructed and stored as a sparse matrix. The degree matrix D is diagonal, so it can be stored as a regular 1-dimensional NumPy array. The procedure for constructing these matrices can be summarized in just a few steps.

1. Initialize A as a sparse $mn \times mn$ matrix and D as a vector with mn entries.
2. For each vertex i ($i = 0, 1, \dots, mn - 1$),
 - (a) Find the set of all vertices J_i such that $\|X(i) - X(j)\| < r$ for each $j \in J_i$. For example, in Figure 6.3 $i = 5$ and $J_5 = \{1, 4, 5, 6, 9\}$.

- (b) Calculate the weights w_{ij} for each $j \in J_i$ according to (6.3) and store them in A .
- (c) Set the i th element of D to be the sum of the weights, $d_i = \sum_{j \in J_i} w_{ij}$.

The most difficult part to implement efficiently is step 2a, computing the neighborhood J_i of the current pixel i . However, the computation only requires knowing the current index i , the radius r , and the height and width m and n of the original image. The following function takes advantage of this fact and returns (as NumPy arrays) both J_i and the distances $\|X(i) - X(j)\|$ for each $j \in J_i$.

```
def get_neighbors(index, radius, height, width):
    """Calculate the flattened indices of the pixels that are within the given
    distance of a central pixel, and their distances from the central pixel.

    Parameters:
        index (int): The index of a central pixel in a flattened image array
                      with original shape (radius, height).
        radius (float): Radius of the neighborhood around the central pixel.
        height (int): The height of the original image in pixels.
        width (int): The width of the original image in pixels.

    Returns:
        (1-D ndarray): the indices of the pixels that are within the specified
                      radius of the central pixel, with respect to the flattened image.
        (1-D ndarray): the euclidean distances from the neighborhood pixels to
                      the central pixel.

    """
    # Calculate the original 2-D coordinates of the central pixel.
    row, col = index // width, index % width

    # Get a grid of possible candidates that are close to the central pixel.
    r = int(radius)
    x = np.arange(max(col - r, 0), min(col + r + 1, width))
    y = np.arange(max(row - r, 0), min(row + r + 1, height))
    X, Y = np.meshgrid(x, y)

    # Determine which candidates are within the given radius of the pixel.
    R = np.sqrt(((X - col)**2 + (Y - row)**2))
    mask = R < radius
    return (X[mask] + Y[mask]*width).astype(np.int), R[mask]
```

To see how this works, consider Figure 6.3 where the original image is 4×4 and the goal is to compute the neighborhood of the pixel $i = 5$.

```
# Compute the neighbors and corresponding distances from the figure.
>>> neighbors_1, distances_1 = get_neighbors(5, 1.2, 4, 4)
>>> print(neighbors_1, distances_1, sep='\n')
[1 4 5 6 9]
[ 1.  1.  0.  1.  1.]

# Increasing the radius from 1.2 to 1.5 results in more neighbors.
```

```
>>> neighbors_2, distances_2 = get_neighbors(5, 1.5, 4, 4)
>>> print(neighbors_2, distances_2, sep='\n')
[ 0  1  2  4  5  6  8  9 10]
[ 1.41421356  1.           1.41421356  1.           0.           1.
  1.41421356  1.           1.41421356]
```

Problem 4. Write a method for the `ImageSegmenter` class that accepts floats r defaulting to 5, σ_B^2 defaulting to .02, and σ_X^2 defaulting to 3. Compute the adjacency matrix A and the degree matrix D according to the weights specified in (6.3).

Initialize A as a `scipy.sparse.lil_array`, which is optimized for incremental construction. Fill in the nonzero elements of A one row at a time. Use `get_neighbors()` at each step to help compute the weights.

(Hint: Try to compute and store an entire row of weights at a time. What does the command `A[5, np.array([1, 4, 5, 6, 9])] = weights` do?)

Finally, convert A to a `scipy.sparse.csc_array`, which is faster for computations. Then return A and D .

Use `blue_heart.png` to test A and D , saved as `HeartMatrixA.npz` and `HeartMatrixD.npy` datafiles.

Segmenting the Graph

With an image represented as a graph G , the goal is to now split G into two distinct connected components by removing edges from the existing graph. This is called *cutting* G , and the set of edges that are removed is called the *cut*. The cut with the least weight will best segment the image.

Let D be the degree matrix and L be the Laplacian matrix of G . Shi and Malik [SM00] proved that the eigenvector corresponding to the second smallest¹ eigenvalue of $D^{-1/2}LD^{-1/2}$ can be used to minimize the cut: the indices of its positive entries are the indices of the pixels in the flattened image which belong to one segment, and the indices of its negative entries are the indices of the pixels which belong to the other segment. In this context $D^{-1/2}$ refers to element-wise exponentiation, so the (i, j) th entry of $D^{-1/2}$ is $1/\sqrt{d_{ij}}$.

Because A is $mn \times mn$, the desired eigenvector has mn entries. Reshaping the eigenvector to be $m \times n$ allows it to align with the original image. Use the reshaped eigenvector to create a boolean mask that indexes one of the segments. That is, construct a $m \times n$ array where the entries belonging to one segment are `True` and the other entries are `False`.

```
>>> x = np.arange(-5, 5).reshape((5, 2)).T
>>> print(x)
[[ -5 -3 -1  1  3]
 [ -4 -2  0  2  4]]

# Construct a boolean mask of x describing which entries of x are positive.
>>> mask = x > 0
>>> print(mask)
```

¹Both D and L are symmetric matrices, so all eigenvalues of $D^{-1/2}LD^{-1/2}$ are real, and therefore “the second smallest one” is well-defined.

```

[[False False False  True  True]
 [False False False  True  True]]

# Use the mask to zero out all of the nonpositive entries of x.
>>> x * mask
array([[0, 0, 0, 1, 3],
       [0, 0, 0, 2, 4]])

```

Problem 5. Write a method for the `ImageSegmenter` class that accepts an adjacency matrix A as a `scipy.sparse.csc_array` and a degree matrix D as a 1-D NumPy array. Construct an $m \times n$ boolean mask describing the segments of the image.

1. Compute the Laplacian L with `scipy.sparse.csgraph.laplacian()` or by converting D to a sparse diagonal matrix and computing $L = D - A$ (do not use your function from Problem 1 unless it works correctly and efficiently for sparse matrices).
2. Construct $D^{-1/2}$ as a sparse diagonal matrix using D and `scipy.sparse.diags()`, then compute $D^{-1/2}LD^{-1/2}$. Use `@` or the `dot()` method of the sparse matrix for the matrix multiplication, **not** `np.dot()`.
3. Use `scipy.sparse.linalg.eigsh()` to compute the eigenvector corresponding to the second-smallest eigenvalue of $D^{-1/2}LD^{-1/2}$. Set the keyword arguments `which="SM"` and `k=2` to compute only the two smallest eigenvalues and their eigenvectors.
4. Reshape the eigenvector as a $m \times n$ matrix and use this matrix to construct the desired boolean mask. Return the mask.

Multiplying the boolean mask component-wise by the original image array produces the *positive segment*, a copy of the original image where the entries that aren't in the segment are set to 0. Computing the *negative segment* requires inverting the boolean mask, then multiplying the inverted mask with the original image array. Finally, if the original image is a $m \times n \times 3$ color image, the mask must be stacked into a $m \times n \times 3$ array to facilitate entry-wise multiplication.

```

>>> mask = np.arange(-5, 5).reshape((5, 2)).T > 0
>>> print(mask)
[[False False False  True  True]
 [False False False  True  True]]

# The mask can be negated with the tilde operator ~.
>>> print(~mask)
[[ True  True  True False False]
 [ True  True  True False False]]

# Stack a mask into a 3-D array with np.dstack().
>>> print(mask.shape, np.dstack((mask, mask, mask)).shape)
(2, 5) (2, 5, 3)

```

Problem 6. Write a method for the `ImageSegmenter` class that accepts floats r , σ_B^2 , and σ_X^2 , with the same defaults as in Problem 4. Call your methods from Problems 4 and 5 to obtain the segmentation mask. Plot the original image, the positive segment, and the negative segment side-by-side in subplots. Your method should work for grayscale or color images.

Use `dream.png` as a test file and compare your results to Figure 6.2.

7

The SVD and Image Compression

Lab Objective: *The Singular Value Decomposition (SVD) is an incredibly useful matrix factorization that is widely used in both theoretical and applied mathematics. The SVD is structured in a way that makes it easy to construct low-rank approximations of matrices, and it is therefore the basis of several data compression algorithms. In this lab we learn to compute the SVD and use it to implement a simple image compression routine.*

The SVD of a matrix A is a factorization $A = U\Sigma V^H$ where U and V have orthonormal columns and Σ is diagonal. The diagonal entries of Σ are called the *singular values* of A and are the square roots of the eigenvalues of $A^H A$. Since $A^H A$ is always positive semidefinite, its eigenvalues are all real and nonnegative, so the singular values are also real and nonnegative. The singular values σ_i are usually sorted in decreasing order so that $\Sigma = \text{diag}(\sigma_1, \sigma_2, \dots, \sigma_n)$ with $\sigma_1 \geq \sigma_2 \geq \dots \geq \sigma_n \geq 0$. The columns \mathbf{u}_i of U , the columns \mathbf{v}_i of V , and the singular values of A satisfy $A\mathbf{v}_i = \sigma_i \mathbf{u}_i$.

Every $m \times n$ matrix A of rank r has an SVD with exactly r nonzero singular values. Like the QR decomposition, the SVD has two main forms.

- **Full SVD:** Denoted $A = U\Sigma V^H$. U is $m \times m$, V is $n \times n$, and Σ is $m \times n$. The first r columns of U span $\mathcal{R}(A)$, and the remaining $n - r$ columns span $\mathcal{N}(A^H)$. Likewise, the first r columns of V span $\mathcal{R}(A^H)$, and the last $m - r$ columns span $\mathcal{N}(A)$.
- **Compact (Reduced) SVD:** Denoted $A = U_1 \Sigma_1 V_1^H$. U_1 is $m \times r$ (the first r columns of U), V_1 is $n \times r$ (the first r columns of V), and Σ_1 is $r \times r$ (the first $r \times r$ block of Σ). This smaller version of the SVD has all of the information needed to construct A and nothing more. The zero singular values and the corresponding columns of U and V are neglected.

$$\begin{array}{ccc}
 U_1 \ (m \times r) & \Sigma_1 \ (r \times r) & V_1^H \ (r \times n) \\
 \left[\begin{array}{ccccccccc}
 \boxed{\mathbf{u}_1 & \cdots & \mathbf{u}_r} & \mathbf{u}_{r+1} & \cdots & \mathbf{u}_m
 \end{array} \right] & \left[\begin{array}{ccccc}
 \sigma_1 & & & & \\
 & \ddots & & & \\
 & & \sigma_r & & \\
 & & & 0 & \\
 & & & & \ddots \\
 & & & & & 0
 \end{array} \right] & \left[\begin{array}{ccccccccc}
 \boxed{\mathbf{v}_1^H} & & & & & & & & \\
 \vdots & & & & & & & & \\
 \boxed{\mathbf{v}_r^H} & & & & & & & & \\
 \mathbf{v}_{r+1}^H & & & & & & & & \\
 \vdots & & & & & & & & \\
 \boxed{\mathbf{v}_n^H} & & & & & & & &
 \end{array} \right] \\
 U \ (m \times m) & \Sigma \ (m \times n) & V^H \ (n \times n)
 \end{array}$$

Finally, the SVD yields an *outer product expansion* of A in terms of the singular values and the columns of U and V ,

$$A = \sum_{i=1}^r \sigma_i \mathbf{u}_i \mathbf{v}_i^H. \quad (7.1)$$

Note that only terms from the compact SVD are needed for this expansion.

Computing the Compact SVD

It is difficult to compute the SVD from scratch because it is an eigenvalue-based decomposition. However, given an eigenvalue solver such as `scipy.linalg.eig()`, the algorithm becomes much simpler. First, obtain the eigenvalues and eigenvectors of $A^H A$, and use these to compute Σ . Since $A^H A$ is normal, it has an orthonormal eigenbasis, so set the columns of V to be the eigenvectors of $A^H A$. Then, since $A \mathbf{v}_i = \sigma_i \mathbf{u}_i$, construct U by setting its columns to be $\mathbf{u}_i = \frac{1}{\sigma_i} A \mathbf{v}_i$.

The key is to sort the singular values and the corresponding eigenvectors in the same manner. In addition, it is computationally inefficient to keep track of the entire matrix Σ since it is a matrix of mostly zeros, so we need only store the singular values as a vector σ . The entire procedure for computing the compact SVD is given below.

Algorithm 1

```

1: procedure COMPACT_SVD( $A$ )
2:    $\lambda, V \leftarrow \text{eig}(A^H A)$                                  $\triangleright$  Calculate the eigenvalues and eigenvectors of  $A^H A$ .
3:    $\sigma \leftarrow \sqrt{\lambda}$                                       $\triangleright$  Calculate the singular values of  $A$ .
4:    $\sigma \leftarrow \text{sort}(\sigma)$                                   $\triangleright$  Sort the singular values from greatest to least.
5:    $V \leftarrow \text{sort}(V)$                                       $\triangleright$  Sort the eigenvectors the same way as in the previous step.
6:    $r \leftarrow \text{count}(\sigma \neq 0)$                              $\triangleright$  Count the number of nonzero singular values (the rank of  $A$ ).
7:    $\sigma_1 \leftarrow \sigma_{:,r}$                                      $\triangleright$  Keep only the positive singular values.
8:    $V_1 \leftarrow V_{:,r}$                                           $\triangleright$  Keep only the corresponding eigenvectors.
9:    $U_1 \leftarrow A V_1 / \sigma_1$                                  $\triangleright$  Construct  $U$  with array broadcasting.
10:  return  $U_1, \sigma_1, V_1^H$ 
```

Problem 1. Write a function that accepts a matrix A and a small error tolerance `tol`. Use Algorithm 1 to compute the compact SVD of A . In step 6, compute r by counting the number of singular values that are greater than `tol`.

Consider the following tips for implementing the algorithm.

- The Hermitian A^H can be computed with `A.conj().T`.
- In step 4, the way that σ is sorted needs to be stored so that the columns of V can be sorted the same way. Consider using `np.argsort()` and fancy indexing to do this, but remember that by default it sorts from least to greatest (not greatest to least).
- Step 9 can be done by looping over the columns of V , but it can be done more easily and efficiently with array broadcasting.

Test your function by calculating the compact SVD for random matrices. Verify that U and V are orthonormal, that $U \Sigma V^H = A$, and that the number of nonzero singular values is the rank of A . You may also want to compare your results to SciPy's SVD algorithm.

```

>>> import numpy as np
>>> from scipy import linalg as la

# Generate a random matrix and get its compact SVD via SciPy.
>>> A = np.random.random((10, 5))
>>> U,s,Vh = la.svd(A, full_matrices=False)
>>> print(U.shape, s.shape, Vh.shape)
(10, 5) (5,) (5, 5)

# Verify that U is orthonormal, U Sigma Vh = A, and the rank is correct.
>>> np.allclose(U.T @ U, np.identity(5))
True
>>> np.allclose(U @ np.diag(s) @ Vh, A)
True
>>> np.linalg.matrix_rank(A) == len(s)
True

```

Visualizing the SVD

An $m \times n$ matrix A defines a linear transformation that sends points from \mathbb{R}^n to \mathbb{R}^m . The SVD decomposes a matrix into two rotations and a scaling, so that any linear transformation can be easily described geometrically. Specifically, V^H represents a rotation, Σ a rescaling along the principal axes, and U another rotation.

Problem 2. Write a function that accepts a 2×2 matrix A . Generate a 2×200 matrix S representing a set of 200 points on the unit circle, with x -coordinates on the top row and y -coordinates on the bottom row (recall the equation for the unit circle in polar coordinates: $x = \cos(\theta)$, $y = \sin(\theta)$, $\theta \in [0, 2\pi]$). Also define the matrix

$$E = [\mathbf{e}_1 \mid \mathbf{0} \mid \mathbf{e}_2] = \begin{bmatrix} 1 & 0 & 0 \\ 0 & 0 & 1 \end{bmatrix},$$

so that plotting the first row of S against the second row of S displays the unit circle, and plotting the first row of E against its second row displays the standard basis vectors in \mathbb{R}^2 .

Compute the full SVD $A = U\Sigma V^H$ using `scipy.linalg.svd()`. Plot four subplots to demonstrate each step of the transformation, plotting S and E , $V^H S$ and $V^H E$, $\Sigma V^H S$ and $\Sigma V^H E$, then $U\Sigma V^H S$ and $U\Sigma V^H E$.

For the matrix

$$A = \begin{bmatrix} 3 & 1 \\ 1 & 3 \end{bmatrix},$$

your function should produce Figure 7.1.

(Hint: Use `plt.axis("equal")` to fix the aspect ratio so that the circles don't appear elliptical.)

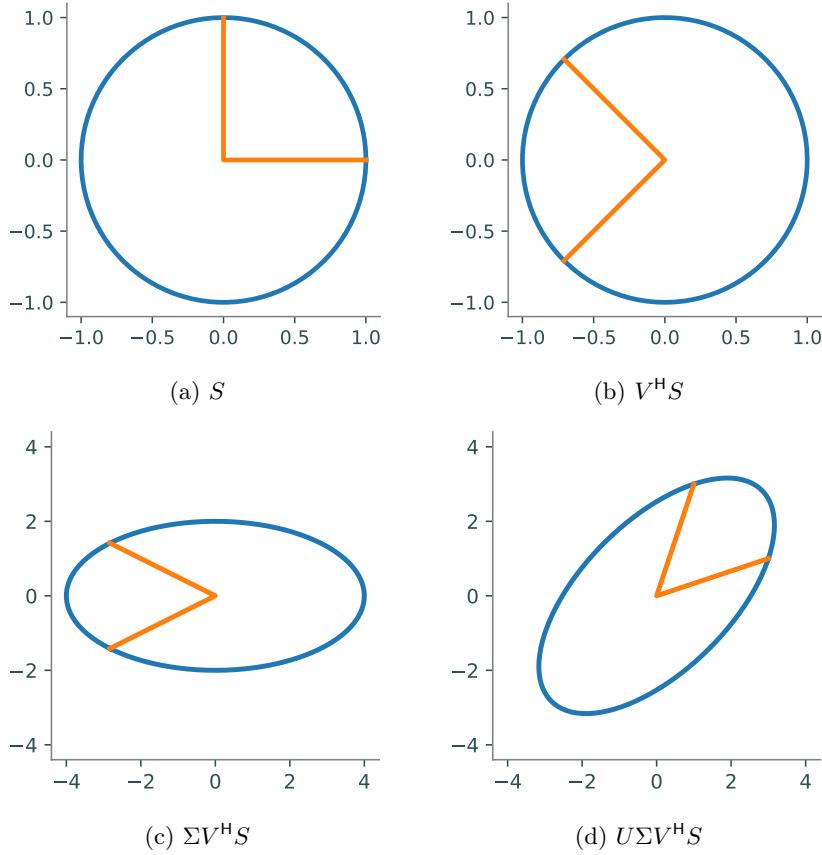

Figure 7.1: Each step in transforming the unit circle and two unit vectors using the matrix A .

Using the SVD for Data Compression

Low-Rank Matrix Approximations

If A is a $m \times n$ matrix of rank $r < \min\{m, n\}$, then the compact SVD offers a way to store A with less memory. Instead of storing all mn values of A , storing the matrices U_1 , Σ_1 and V_1 only requires saving a total of $mr + r + nr$ values. For example, if A is 100×200 and has rank 20, then A has 20,000 values, but its compact SVD only has total 6,020 entries, a significant decrease.

The *truncated SVD* is an approximation to the compact SVD that allows even greater efficiency at the cost of a little accuracy. Instead of keeping all of the nonzero singular values, the truncated SVD only keeps the first $s < r$ singular values, plus the corresponding columns of U and V . In this case, (7.1) becomes

$$A_s = \sum_{i=1}^s \sigma_i \mathbf{u}_i \mathbf{v}_i^H.$$

More precisely, the truncated SVD of A is $A_s = \widehat{U} \widehat{\Sigma} \widehat{V}^H$, where \widehat{U} is $m \times s$, \widehat{V} is $n \times s$, and $\widehat{\Sigma}$ is $s \times s$. The resulting matrix A_s has rank s and is only an approximation to A , since $r - s$ nonzero singular values are neglected.

$$\begin{bmatrix}
 \widehat{U} (m \times s) \\
 \left[\begin{array}{ccccccccc}
 & & & & & & & & \\
 \boxed{\mathbf{u}_1} & \cdots & \boxed{\mathbf{u}_s} & \mathbf{u}_{s+1} & \cdots & \mathbf{u}_r & & & \\
 & & & & & & & & \\
 U_1 (m \times r) & & & & & & & &
 \end{array} \right] \\
 \widehat{\Sigma} (s \times s) \\
 \left[\begin{array}{ccccccccc}
 \sigma_1 & & & & & & & & \\
 & \ddots & & & & & & & \\
 & & \sigma_s & & & & & & \\
 & & & & \sigma_{s+1} & & & & \\
 & & & & & \ddots & & & \\
 & & & & & & \sigma_r & & \\
 \Sigma_1 (r \times r) & & & & & & & &
 \end{array} \right] \\
 \widehat{V}^H (s \times n) \\
 \left[\begin{array}{ccccccccc}
 \mathbf{v}_1^H & & & & & & & & \\
 \vdots & & & & & & & & \\
 \mathbf{v}_s^H & & & & & & & & \\
 \mathbf{v}_{s+1}^H & & & & & & & & \\
 \vdots & & & & & & & & \\
 \mathbf{v}_r^H & & & & & & & & \\
 V_1^H (r \times n) & & & & & & & &
 \end{array} \right]
 \end{bmatrix}$$

The beauty of the SVD is that it makes it easy to select the information that is most important. Larger singular values correspond to columns of U and V that contain more information, so dropping the smallest singular values retains as much information as possible. In fact, given a matrix A , its rank- s truncated SVD approximation A_s is the *best rank s approximation* of A with respect to both the induced 2-norm and the Frobenius norm. This result is called the *Schmidt, Mirsky, Eckhart-Young theorem*, a very significant concept that appears in signal processing, statistics, machine learning, semantic indexing (search engines), and control theory.

Problem 3. Write a function that accepts a matrix A and a positive integer s .

1. Use your function from Problem 1 or `scipy.linalg.svd()` to compute the compact SVD of A , then form the truncated SVD by stripping off the appropriate columns and entries from U_1 , Σ_1 , and V_1 . Return the best rank s approximation A_s of A (with respect to the induced 2-norm and Frobenius norm).
2. Also return the number of entries required to store the truncated form $\widehat{U}\widehat{\Sigma}\widehat{V}^H$ (where $\widehat{\Sigma}$ is stored as a one-dimensional array, not the full diagonal matrix). Note that the number of entries needed will be the sum of the number of entries of each matrix. The number of entries stored in NumPy array can be accessed by its `size` attribute.

```
>>> A = np.random.random((20, 20))
>>> A.size
400
```

3. If s is greater than the number of nonzero singular values of A (meaning $s > \text{rank}(A)$), raise a `ValueError`.

Use `np.linalg.matrix_rank()` to verify the rank of your approximation.

UNIT TEST

Write a unit test for Problem 3 to check your low rank SVD approximation. The unit test can be found in the file `test_svd_image_compression.py`, and you will edit the problem `test_svd_approx`.

There is an example unit test for Problem 1 to help you make your unit test.

Error of Low-Rank Approximations

Another result of the Schmidt, Mirsky, Eckhart-Young theorem is that the exact 2-norm error of the best rank- s approximation A_s for the matrix A is the $(s+1)$ th singular value of A :

$$\|A - A_s\|_2 = \sigma_{s+1}. \quad (7.2)$$

This offers a way to approximate A within a desired error tolerance ε : choose s such that σ_{s+1} is the largest singular value that is less than ε , then compute A_s . This A_s throws away as much information as possible without violating the property $\|A - A_s\|_2 < \varepsilon$.

Problem 4. Write a function that accepts a matrix A and an error tolerance ε .

1. Compute the compact SVD of A , then use (7.2) to compute the lowest rank approximation A_s of A with 2-norm error less than ε . Avoid calculating the SVD more than once.
(Hint: `np.argmax()`, `np.where()`, and/or fancy indexing may be useful.)
2. As in the previous problem, also return the number of entries needed to store the resulting approximation A_s via the truncated SVD.
3. If ε is less than or equal to the smallest singular value of A , raise a `ValueError`; in this case, A cannot be approximated within the tolerance by a matrix of lesser rank.

This function should be close to identical to the function from Problem 3, but with the extra step of identifying the appropriate s . Construct test cases to validate that $\|A - A_s\|_2 < \varepsilon$.

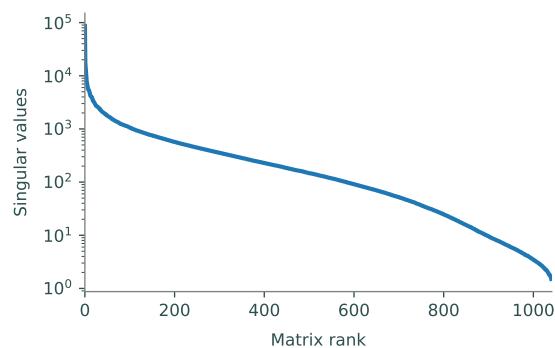

Image Compression

Images are stored on a computer as matrices of pixel values. Sending an image over the internet or a text message can be expensive, but computing and sending a low-rank SVD approximation of the image can considerably reduce the amount of data sent while retaining a high level of image detail. Successive levels of detail can be sent after the initial low-rank approximation by sending additional singular values and the corresponding columns of V and U .

Examining the singular values of an image gives us an idea of how low-rank the approximation can be. Figure 7.2 shows the image in `hubble_gray.jpg` and a log plot of its singular values. The plot in 7.2b is typical for a photograph—the singular values start out large but drop off rapidly. In this rank 1041 image, 913 of the singular values are 100 or more times smaller than the largest singular value. By discarding these relatively small singular values, we can retain all but the finest image details, while storing only a rank 128 image. This is a **huge** reduction in data size.

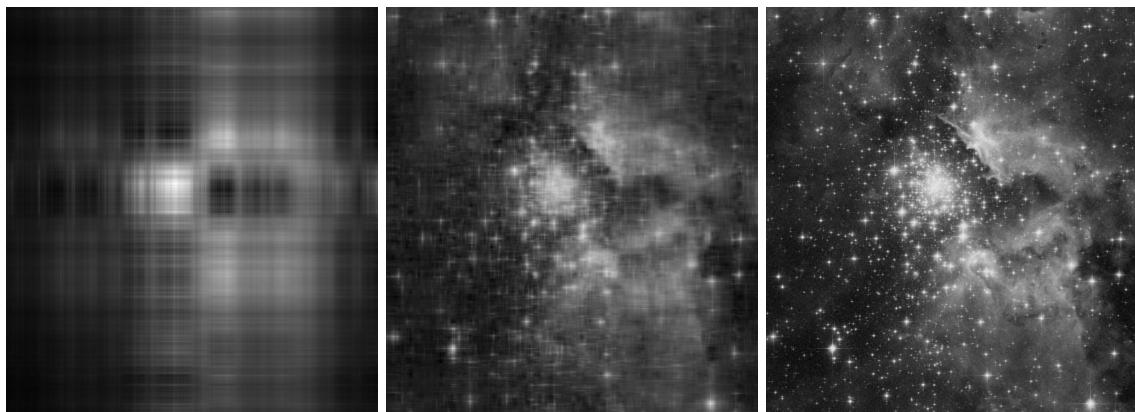

(a) NGC 3603 (Hubble Space Telescope).

(b) Singular values on a log scale.

Figure 7.2

Figure 7.3 shows several low-rank approximations of the image in Figure 7.2a. Even at a low rank the image is recognizable. By rank 120, the approximation differs very little from the original.

(a) Rank 2

(b) Rank 20

(c) Rank 120

Figure 7.3

Grayscale images are stored on a computer as 2-dimensional arrays, while color images are stored as 3-dimensional arrays—one layer each for red, green, and blue arrays. To read and display images, use `imageio.v3.imread()` and `plt.imshow()`. Images are read in as integer arrays with entries between 0 and 255 (`dtype=np.uint8`), but `plt.imshow()` works better if the image is an array of floats in the interval [0, 1]. Scale the image properly by dividing the array by 255.

```
>>> from imageio.v3 import imread
>>> from matplotlib import pyplot as plt

# Send the RGB values to the interval (0,1).
>>> image_gray = imread("hubble_gray.jpg") / 255.
>>> image_gray.shape           # Grayscale images are 2-d arrays.
(1158, 1041)
>>> image_color = imread("hubble.jpg") / 255.
```

```
>>> image_color.shape          # Color images are 3-d arrays.
(1158, 1041, 3)

# The final axis has 3 layers for red, green, and blue values.
>>> red_layer = image_color[:, :, 0]
>>> red_layer.shape
(1158, 1041)

# Display a gray image.
>>> plt.imshow(red_layer, cmap="gray")
>>> plt.axis("off")           # Turn off axis ticks and labels.
>>> plt.show()

# Display a color image.
>>> plt.imshow(image_color)    # cmap=None by default.
>>> plt.axis("off")
>>> plt.show()
```

Problem 5. Write a function that accepts the name of an image file and an integer s . Use your function from Problem 3, to compute the best rank- s approximation of the image. Plot the original image and the approximation in separate subplots. In the figure title, report the difference in number of entries required to store the original image and the approximation (use `plt.suptitle()`).

Your function should be able to handle both grayscale and color images. Read the image in and check its dimensions to see if it is color or not. Grayscale images can be approximated directly since they are represented by 2-dimensional arrays. For color images, let R , G , and B be the matrices for the red, green, and blue layers of the image, respectively. Calculate the low-rank approximations R_s , G_s , and B_s separately, then put them together in a new 3-dimensional array of the same shape as the original image.

(Hint: `np.dstack()` may be useful for putting the color layers back together.)

Finally, it is possible for the low-rank approximations to have values slightly outside the valid range of RGB values. Set any values outside of the interval $[0, 1]$ to the closer of the two boundary values.

(Hint: fancy indexing and/or `np.clip()` may be useful here.)

To check, compressing `hubble_gray.jpg` with a rank 20 approximation should appear similar to Figure 7.3b and save 1,161,478 matrix entries.

Additional Material

More on Computing the SVD

For an $m \times n$ matrix A of rank $r < \min\{m, n\}$, the compact SVD of A neglects last $m - r$ columns of U and the last $n - r$ columns of V . The remaining columns of each matrix can be calculated by using Gram-Schmidt orthonormalization. If $m < r < n$ or $n < r < m$, only one of U_1 and V_1 will need to be filled in to construct the full U or V . Computing these extra columns is one way to obtain a basis for $\mathcal{N}(A^H)$ or $\mathcal{N}(A)$.

Algorithm 1 begins with the assumption that we have a way to compute the eigenvalues and eigenvectors of $A^H A$. Computing eigenvalues is a notoriously difficult problem, and computing the SVD from scratch without an eigenvalue solver is much more difficult than the routine described by Algorithm 1. The procedure involves two phases:

1. Factor A into $A = U_a B V_a^H$ where B is bidiagonal (only nonzero on the diagonal and the first superdiagonal) and U_a and V_a are orthonormal. This is usually done via *Golub-Kahan Bidiagonalization*, which uses Householder reflections, or *Lawson-Hanson-Chan bidiagonalization*, which relies on the QR decomposition.
2. Factor B into $B = U_b \Sigma V_b^H$ by the QR algorithm or a divide-and-conquer algorithm. Then the SVD of A is given by $A = (U_a U_b) \Sigma (V_a V_b)^H$.

For more details, see Lecture 31 of [TB97] or Section 5.4 of *Applied Numerical Linear Algebra* by James W. Demmel.

Animating Images with Matplotlib

Matplotlib can be used to animate images that change over time. For instance, we can show how the low-rank approximations of an image change as the rank s increases, showing how the image is recovered as more ranks are added. Try using the following code to create such an animation.

```
from matplotlib import pyplot as plt
from matplotlib.animation import FuncAnimation

def animate_images(images):
    """Animate a sequence of images. The input is a list where each
    entry is an array that will be one frame of the animation.
    """
    fig = plt.figure()
    plt.axis("off")
    im = plt.imshow(images[0], animated=True)

    def update(index):
        plt.title("Rank {} Approximation".format(index))
        im.set_array(images[index])
        return im,           # Note the comma!

    a = FuncAnimation(fig, update, frames=len(images), blit=True)
    plt.show()
```

See https://matplotlib.org/examples/animation/dynamic_image.html for another example.

Facial Recognition

Lab Objective: Facial recognition algorithms attempt to match a person's portrait to a database of many portraits. Facial recognition is becoming increasingly important in security, law enforcement, artificial intelligence, and other areas. Though humans can easily match pictures to people, computers are beginning to surpass humans at facial recognition. In this lab, we implement a basic facial recognition system that relies on eigenvectors and the SVD to efficiently determine the difference between faces.

Preparing an Image Database

The `faces94` face image dataset¹ contains several photographs of 153 people, organized into folders by person. To perform facial recognition on this dataset, select one image per person and convert these images into a database. For this particular facial recognition algorithm, the entire database can be stored in just a few NumPy arrays.

Digital images are stored on computers as arrays of pixels. Therefore, an $m \times n$ image can be stored in memory as an $m \times n$ matrix or, equivalently, as an mn -vector by concatenating the rows of the matrix. Then a collection of k images can be stored as a single $mn \times k$ matrix F , where each column of F represents a single image. That is, if

$$F = \left[\begin{array}{c|c|c|c} & & & \\ \mathbf{f}_1 & \mathbf{f}_2 & \cdots & \mathbf{f}_k \\ & & & \end{array} \right],$$

then each \mathbf{f}_i is a mn -vector representing a single image.

The following function obtains one image for each person in the `faces94` dataset and converts the collection of images into an $mn \times k$ matrix F described above.

```
import os
import numpy as np
from imageio.v3 import imread

def get_faces(path="."):
    # Traverse the directory and get one image per subdirectory.
```

¹See <https://cmp.felk.cvut.cz/~spacelib/faces/faces94.html>.

```

faces = []
for (dirpath, dirnames, filenames) in os.walk(path):
    for fname in filenames:
        if fname[-3:]=="jpg":      # Only get jpg images.
            # Load the image, convert it to grayscale,
            # and flatten it into a vector.
            faces.append(np.ravel(imread(dirpath+"/"+fname, mode='F')))
            break
# Put all the face vectors column-wise into a matrix.
return np.transpose(faces)

```

Problem 1. Write a function that accepts an image as a flattened mn -vector, along with its original dimensions m and n . Use `np.reshape()` to convert the flattened image into its original $m \times n$ shape and display the result with `plt.imshow()`.

(Hint: use `cmap="gray"` in `plt.imshow()` to display images in grayscale.)

Unzip the `faces94.zip` archive and use `get_faces()` to construct F . Each `faces94` image is 200×180 , and there are 153 people in the dataset, so F should be 36000×153 . Use your function to display one of the images stored in F .

The Eigenfaces Method

With the image database F , we could construct a simple facial recognition system with the following strategy. Let \mathbf{g} be an mn -vector representing an unknown face that is not part of the database F . Then the \mathbf{f}_i that minimizes $\|\mathbf{g} - \mathbf{f}_i\|_2$ is the matching face. Unfortunately, computing $\|\mathbf{g} - \mathbf{f}_i\|_2$ for each i is very computationally expensive, especially if the images are high-resolution and/or the database contains a large number of images. The *eigenfaces method* is a way to reduce the computational cost of finding the closest matching face by focusing on only the most important features of each face. Because the method ignores less significant facial features, it is also usually more accurate than the naïve method.

The first step of the algorithm is to shift the images by the *mean face*. Shifting a set of data by the mean exaggerates the distinguishing features of each entry. In the context of facial recognition, shifting by the mean accentuates the unique features of each face. For the images vectors stored in F , the mean face $\boldsymbol{\mu}$ is defined to be the element-wise average of the \mathbf{f}_i :

$$\boldsymbol{\mu} = \frac{1}{k} \sum_{i=1}^k \mathbf{f}_i.$$

Hence, the i th mean-shifted face vector $\bar{\mathbf{f}}_i$ is given by

$$\bar{\mathbf{f}}_i = \mathbf{f}_i - \boldsymbol{\mu}.$$

Next, define \bar{F} as the $mn \times k$ matrix whose columns are given by the mean-shifted face vectors,

$$\bar{F} = \left[\begin{array}{c|c|c|c} \bar{\mathbf{f}}_1 & \bar{\mathbf{f}}_2 & \cdots & \bar{\mathbf{f}}_k \end{array} \right].$$

(a) The mean face. (b) An original face. (c) A mean-shifted face.

Figure 8.1

Problem 2. Write a class called `FacialRec` whose constructor accepts a path to a directory of images. In the constructor, use `get_faces()` to construct F , then compute the mean face μ and the shifted faces \bar{F} . Store each array as an attribute.

(Hint: Both μ and \bar{F} can be computed in a single line of code by using NumPy functions and/or array broadcasting.)

Use your function from Problem 1 to visualize the mean face, and compare it to Figure 8.1a. Also display an original face and its corresponding mean-shifted face. Compare your results with Figures 8.1b and 8.1c.

To increase computational efficiency and minimize storage, the face vectors can be represented with fewer values by projecting \bar{F} onto a lower-dimensional subspace. Let s be a natural number such that $s < r$, where r is the rank of \bar{F} . By projecting \bar{F} onto an s -dimensional subspace, each face can be stored with only s values.

Specifically, let $U\Sigma V^H$ be the compact SVD of \bar{F} with rank r , which can also be represented by

$$\bar{F} = \sum_{i=1}^r \sigma_i \mathbf{u}_i \mathbf{v}_i^H.$$

The first r columns of U form a basis for the range of \bar{F} . Recall that the Schmidt, Mirsky, Eckart-Young Theorem states that the matrix

$$\bar{F}_s = \sum_{i=1}^s \sigma_i \mathbf{u}_i \mathbf{v}_i^H$$

is the best rank- s approximation of \bar{F} for each $s < r$. This means that $\|\bar{F} - \bar{F}_s\|$ is minimized against all other $\|\bar{F} - B\|$ where B has rank s . As a consequence of this theorem, the first s columns of U form a basis that provides the “best” s -dimensional subspace for approximating \bar{F} .

The s basis vectors $\mathbf{u}_1, \dots, \mathbf{u}_s$ are commonly called the *eigenfaces* because they are eigenvectors of $\bar{F}\bar{F}^T$ and because they resemble face images. Each original face image can be efficiently represented in terms of these eigenfaces. See Figure 8.2 for visualizations of some of the eigenfaces for the `facesd94` data set.

Figure 8.2: The first, 50th, and 100th eigenfaces.

In general, the lower eigenfaces provide a more general information of a face and higher-ordered eigenfaces provide the details necessary to distinguish particular faces [MMH04]. These eigenfaces will be used to construct the face images in the dataset. The more eigenfaces used, the more detailed the resulting image will be.

Next, let U_s be the matrix with the first s eigenfaces as columns. Since the eigenfaces $\{\mathbf{u}_i\}_{i=1}^s$ form an orthonormal set, U_s is an orthonormal matrix (independent of s) and hence $U_s^\top U_s = I$. The matrix $P_s = U_s U_s^\top$ projects vectors in \mathbb{R}^{mn} to the subspace spanned by the orthonormal basis $\{\mathbf{u}_i\}_{i=1}^s$, and the change of basis matrix U_s^\top puts the projection in terms of the basis of eigenfaces. Thus the projection $\hat{\mathbf{f}}_i$ of $\bar{\mathbf{f}}_i$ in terms of the basis of eigenfaces is given by

$$\hat{\mathbf{f}}_i = U_s^\top P_s \bar{\mathbf{f}}_i = U_s^\top U_s U_s^\top \bar{\mathbf{f}}_i = U_s^\top \bar{\mathbf{f}}_i. \quad (8.1)$$

Note carefully that though the shifted image $\bar{\mathbf{f}}_i$ has mn entries, the projection $\hat{\mathbf{f}}_i$ has only s entries since U_s is $mn \times s$. Likewise, the matrix \hat{F} that has the projections $\hat{\mathbf{f}}_i$ as columns is $s \times k$, and

$$\hat{F} = U_s^\top F. \quad (8.2)$$

Problem 3. In the constructor of `FacialRec`, calculate the compact SVD of \bar{F} and save the matrix U as an attribute. Compare the computed eigenfaces (the columns of U) to Figure 8.2.

Also write a method that accepts a vector of length mn or an $mn \times \ell$ matrix, as well as an integer $s < mn$. Construct U_s by taking the first s columns of U , then use (8.1) or (8.2) to calculate the projection of the input vector or matrix onto the span of the first s eigenfaces. (Hint: this method should be implemented with a single line of code.)

Reducing the mean-shifted face image $\bar{\mathbf{f}}_i$ to the lower-dimensional projection $\hat{\mathbf{f}}_i$ drastically reduces the computational cost of the facial recognition algorithm, but this efficiency gain comes at a price. A projection image only approximates the corresponding original image, but as long as s isn't too small, the approximation is usually good enough for the algorithm to work well. Before completing the facial recognition system, we reconstruct some of these projections to visualize the amount of information lost.

From (8.1), since U_s^\top projects $\bar{\mathbf{f}}_i$ and performs a change of basis to get $\hat{\mathbf{f}}_i$, its transpose U_s puts $\hat{\mathbf{f}}_i$ back into the original basis with as little error as possible. That is,

$$U_s \hat{\mathbf{f}}_i \approx \bar{\mathbf{f}}_i = \mathbf{f}_i - \boldsymbol{\mu},$$

so that we have the approximation

$$\tilde{\mathbf{f}}_i = U_s \hat{\mathbf{f}}_i + \boldsymbol{\mu} \approx \mathbf{f}_i. \quad (8.3)$$

This $\tilde{\mathbf{f}}_i$ is called the *reconstruction* of \mathbf{f}_i .

(a) A reconstruction with $s = 5$. (b) A reconstruction with $s = 19$. (c) A reconstruction with $s = 75$.

Figure 8.3: An image rebuilt with various numbers of eigenfaces. The image is already recognizable when it is reconstructed with only 19 eigenfaces, less than an eighth of the 153 eigenfaces corresponding to nonzero eigenvalues or $\bar{F}\bar{F}^T$. Note the similarities between this method and regular image compression via the truncated SVD.

Problem 4. Instantiate a `FacialRec` object that draws from the `faces94` dataset. Select one of the shifted images $\bar{\mathbf{f}}_i$. For at least 4 values of s , use your method from Problem 3 to compute the corresponding s -projection $\hat{\mathbf{f}}_i$, then use (8.3) to compute the reconstruction $\tilde{\mathbf{f}}_i$. Display the various reconstructions and the original image. Compare your results to Figure 8.3

Matching Faces

Let \mathbf{g} be a vector representing an unknown face that is not part of the database. We determine which image in the database is most like \mathbf{g} by comparing $\hat{\mathbf{g}}$ to each of the $\hat{\mathbf{f}}_i$. First, shift \mathbf{g} by the mean to obtain $\bar{\mathbf{g}}$, then project $\bar{\mathbf{g}}$ using a given number of eigenfaces:

$$\hat{\mathbf{g}} = U_s^T \bar{\mathbf{g}} = U_s^T (\mathbf{g} - \boldsymbol{\mu}) \quad (8.4)$$

Next, we determine which $\hat{\mathbf{f}}_i$ is closest to $\hat{\mathbf{g}}$. By setting

$$j = \underset{i}{\operatorname{argmin}} \|\hat{\mathbf{f}}_i - \hat{\mathbf{g}}\|_2, \quad (8.5)$$

we have that the j th face image \mathbf{f}_j is the approximate best match for \mathbf{g} . Again, since $\hat{\mathbf{f}}_i$ and $\hat{\mathbf{g}}$ only have s entries, the computation in (8.5) is much cheaper than comparing the raw \mathbf{f}_i to \mathbf{g} .

Problem 5. Write a method for the `FacialRec` class that accepts an image vector \mathbf{g} and an integer s . Use your method from Problem 3 to compute \hat{F} and $\hat{\mathbf{g}}$ for the given s , then use (8.5) to determine the best matching face in the database. Return the index of the matching face. (Hint: `scipy.linalg.norm()` and `np.argmin()` may be useful.)

NOTE

This facial recognition system works by solving a *nearest neighbor search*, since the goal is to find the \mathbf{f}_i that is “nearest” to the input image \mathbf{g} . Nearest neighbor searches can be performed more efficiently with the use of a *k-d tree*, a binary search tree for storing vectors. The system could also be called a *k-neighbors classifier* with $k = 1$.

Problem 6. Write a method for the `FacialRec` class that accepts an flat image vector \mathbf{g} , an integer s , and the original dimensions of \mathbf{g} . Use your method from Problem 5 to find the index j of the best matching face, then display the original face \mathbf{g} alongside the best match \mathbf{f}_j .

The following generator yields random faces from `faces94` that can be used as test cases.

```
def sample_faces(num_faces, path=".//faces94"):
    # Get the list of possible images.
    files = []
    for (dirpath, dirnames, filenames) in os.walk(path):
        for fname in filenames:
            if fname[-3:]=="jpg":      # Only get jpg images.
                files.append(dirpath+"/"+fname)

    # Get a subset of the image names and yield the images one at a time.
    test_files = np.random.choice(files, num_faces, replace=False)
    for fname in test_files:
        yield np.ravel(imread(fname, mode='F'))
```

The `yield` keyword is like a `return` statement, but the next time the generator is called, it will resume immediately after the last `yield` statement.^a

Use `sample_faces()` to get at least 5 random faces from `faces94`, and match each random face to the database with $s = 38$. Iterate through the random faces with the following syntax.

```
for test_image in sample_faces(5):
    # 'test_image' is a now flattened face vector.
```

^aSee the Python Essentials lab on Profiling for more on generators.

Although there are other approaches to facial recognition that utilize more complex techniques, the method of eigenfaces remains a wonderfully simple and effective solution.

Additional Material

Improvements on the Facial Recognition System with Eigenfaces

The `FacialRec` class does its job well, but it could be improved in several ways. Here are a few ideas.

- The most computationally intensive part of the algorithm is computing \hat{F} . Instead of recomputing \hat{F} every time the method from Problem 5 is called, store \hat{F} and s as attributes the first time the method is called. In subsequent calls, only recompute \hat{F} if the user specifies a different value for s .
- Load a `scipy.spatial.KDTree` object with \hat{F} and use its `query()` method to compute (8.5). Building a kd-tree is expensive, so be sure to only build a new tree when necessary (i.e., the user specifies a new value for s).
- Include an error tolerance ε in the method for Problem 5. If $\|\mathbf{f}_j - \mathbf{g}\| > \varepsilon$, print a message or raise an exception to indicate that there is no suitable match for \mathbf{g} in the database. In this case, add \mathbf{g} to the database for future reference.
- Generalize the system by turning it into a k -neighbors classifier. In the constructor, add several faces per person to the database (this requires modifying `get_faces()`). Assign each individual a unique ID so that the system knows which faces correspond to the same person. Modify the method from Problem 5 so that it also accepts an integer k , then use `scipy.spatial.KDTree` to find the k nearest images to \mathbf{g} . Choose the ID that belongs to the most nearest neighbors, then return an index that corresponds to an individual with that ID.

In other words, choose the k faces \mathbf{f}_i that give the smallest values of $\|\mathbf{f}_i - \hat{\mathbf{g}}\|_2$. These faces then get to vote on which person \mathbf{g} belongs to.

- Improve the user interface of the class by modifying the method from Problem 6 so that it accepts a file name to read from instead of an array. A few lines of code from `get_faces()` or `sample_faces()` might be helpful for this.

Other Methods for Facial Recognition

The method of facial recognition presented here is more formally called *principal component analysis (PCA) using eigenfaces*. Several other machine learning and optimization techniques, such as linear discriminant analysis (LDA), elastic matching, dynamic link matching, and hidden Markov models (HMMs) have also been applied to the facial recognition problem. Other techniques focus on getting better information about the faces in the first place, the most prevalent being 3-dimensional recognition and thermal imaging. See https://en.wikipedia.org/wiki/Facial_recognition_system for a good survey of different approaches to the facial recognition problem.

9

Differentiation

Lab Objective: Derivatives are central in many applications. Depending on the application and on the available information, the derivative may be calculated symbolically, numerically, or with differentiation software. In this lab we explore these three ways to take a derivative, discuss what settings they are each appropriate for, and demonstrate their strengths and weaknesses.

Symbolic Differentiation

The derivative of a known mathematical function can be calculated symbolically with SymPy. This method is the most precise way to take a derivative, but it is computationally expensive and requires knowing the closed form formula of the function. Use `sy.diff()` to take a symbolic derivative.

```
>>> import sympy as sy

>>> x = sy.symbols('x')
>>> sy.diff(x**3 + x, x)      # Differentiate x^3 + x with respect to x.
3*x**2 + 1
```

Problem 1. Write a function that defines $f(x) = (\sin(x) + 1)^{\sin(\cos(x))}$ and takes its symbolic derivative with respect to x using SymPy. Lambdify the resulting function so that it can accept NumPy arrays and return the resulting function handle.

Hint: You can test your function by plotting f and its derivative f' over the domain $[-\pi, \pi]$. It may be helpful to move the bottom spine to 0 so you can see where the derivative crosses the x -axis. Note: Do NOT include this in the final code for this problem.

```
>>> from matplotlib import pyplot as plt

>>> ax = plt.gca()
>>> ax.spines["bottom"].set_position("zero")
```

Numerical Differentiation

One definition for the derivative of a function $f : \mathbb{R} \rightarrow \mathbb{R}$ at a point x_0 is

$$f'(x_0) = \lim_{h \rightarrow 0} \frac{f(x_0 + h) - f(x_0)}{h}.$$

Since this definition relies on h approaching 0, choosing a small, fixed value for h approximates $f'(x_0)$:

$$f'(x_0) \approx \frac{f(x_0 + h) - f(x_0)}{h}. \quad (9.1)$$

This approximation is called the *first order forward difference quotient*. Using the points x_0 and $x_0 - h$ in place of $x_0 + h$ and x_0 , respectively, results in the *first order backward difference quotient*,

$$f'(x_0) \approx \frac{f(x_0) - f(x_0 - h)}{h}. \quad (9.2)$$

Forward difference quotients use values of f at x_0 and points greater than x_0 , while backward difference quotients use the values of f at x_0 and points less than x_0 . A *centered difference quotient* uses points on either side of x_0 , and typically results in a better approximation than the one-sided quotients. Combining (9.1) and (9.2) yields the *second order centered difference quotient*,

$$f'(x_0) = \frac{1}{2}f'_{+}(x_0) + \frac{1}{2}f'_{-}(x_0) \approx \frac{f(x_0 + h) - f(x_0)}{2h} + \frac{f(x_0) - f(x_0 - h)}{2h} = \frac{f(x_0 + h) - f(x_0 - h)}{2h}.$$

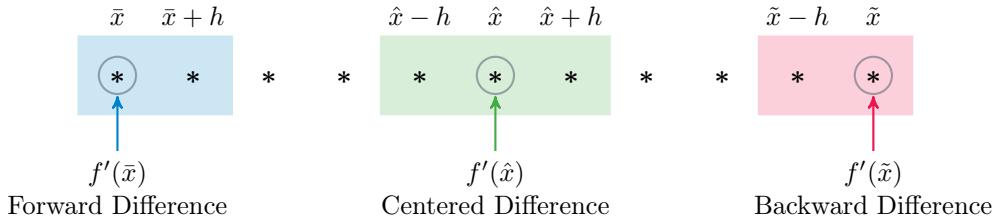

Figure 9.1

NOTE

The finite difference quotients in this section all approximate the first derivative of a function. The terms *first order* and *second order* refers to how quickly the approximation converges on the actual value of $f'(x_0)$ as h approaches 0, not to how many derivatives are being taken.

There are finite difference quotients for approximating higher order derivatives, such as f'' or f''' . For example, the centered difference quotient

$$f''(x_0) \approx \frac{f(x_0 - h) - 2f(x_0) + f(x_0 + h)}{h^2}$$

approximates the second derivative. This particular quotient is important for finite difference methods that approximate numerical solutions to some partial differential equations.

While we do not derive them here, there are other finite difference quotients that use more points to approximate the derivative, some of which are listed below. Using more points generally results in better convergence properties.

Type	Order	Formula
Forward	1	$\frac{f(x_0+h) - f(x_0)}{h}$
	2	$\frac{-3f(x_0) + 4f(x_0+h) - f(x_0+2h)}{2h}$
Backward	1	$\frac{f(x_0) - f(x_0-h)}{h}$
	2	$\frac{3f(x_0) - 4f(x_0-h) + f(x_0-2h)}{2h}$
Centered	2	$\frac{f(x_0+h) - f(x_0-h)}{2h}$
	4	$\frac{f(x_0-2h) - 8f(x_0-h) + 8f(x_0+h) - f(x_0+2h)}{12h}$

Table 9.1: Common finite difference quotients for approximating $f'(x_0)$.

Problem 2. Write a function for each of the finite difference quotients listed in Table 9.1. Each function should accept a function handle f , an array of points \mathbf{x} , and a float h ; each should return an array of the difference quotients evaluated at each point in \mathbf{x} .

To test your functions, approximate the derivative of $f(x) = (\sin(x) + 1)^{\sin(\cos(x))}$ at each point of a domain over $[-\pi, \pi]$. Plot the results and compare them to the results of Problem 1.

Convergence of Finite Difference Quotients

Finite difference quotients are typically derived using Taylor's formula. This method also shows how the accuracy of the approximation increases as $h \rightarrow 0$:

$$f(x_0 + h) = f(x_0) + f'(x_0)h + R_2(h) \implies \frac{f(x_0 + h) - f(x_0)}{h} - f'(x_0) = \frac{R_2(h)}{h}, \quad (9.3)$$

where $R_2(h) = h^2 \int_0^1 (1-t)f''(x_0 + th) dt$. Thus the absolute error of the first order forward difference quotient is

$$\left| \frac{R_2(h)}{h} \right| = |h| \left| \int_0^1 (1-t)f''(x_0 + th) dt \right| \leq |h| \int_0^1 |1-t||f''(x_0 + th)| dt.$$

If f'' is continuous, then for any $\delta > 0$, setting $M = \sup_{x \in (x_0 - \delta, x_0 + \delta)} f''(x)$ guarantees that

$$\left| \frac{R_2(h)}{h} \right| \leq |h| \int_0^1 M dt = M|h| \in O(h).$$

whenever $|h| < \delta$. That is, the error decreases at the same rate as h . If h gets twice as small, the error does as well. This is what is meant by a *first order* approximation. In a *second order* approximation, the absolute error is $O(h^2)$, meaning that if h gets twice as small, the error gets four times smaller.

NOTE

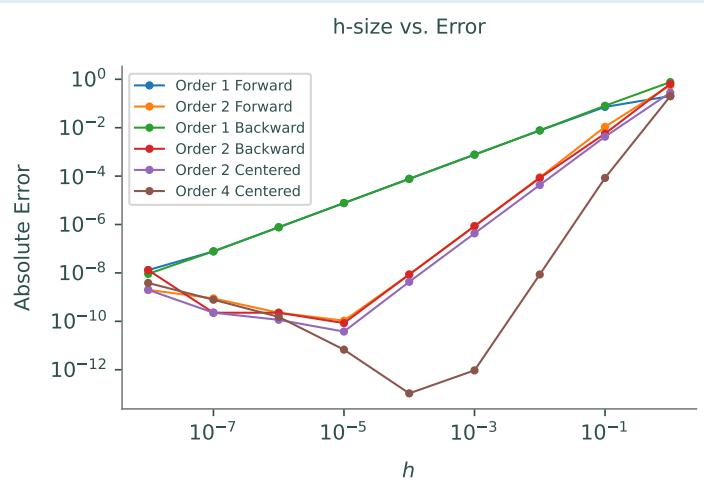

The notation $O(f(n))$ is commonly used to describe the temporal or spatial complexity of an algorithm. In that context, a $O(n^2)$ algorithm is much worse than a $O(n)$ algorithm. However, when referring to error, a $O(h^2)$ algorithm is **better** than a $O(h)$ algorithm because it means that the accuracy improves faster as h decreases.

Problem 3. Write a function that accepts a point x_0 at which to compute the derivative of $f(x) = (\sin(x) + 1)^{\sin(\cos(x))}$. Use your function from Problem 1 to compute the exact value of $f'(x_0)$. Then use each your functions from Problem 2 to get an approximate derivative $\tilde{f}'(x_0)$ for $h = 10^{-8}, 10^{-7}, \dots, 10^{-1}, 1$. Track the absolute error $|f'(x_0) - \tilde{f}'(x_0)|$ for each trial, then plot the absolute error against h on a log-log scale (use `plt.loglog()`).

Instead of using `np.linspace()` to create an array of h values, use `np.logspace()`. This function generates logarithmically spaced values between two powers of 10.

```
>>> np.logspace(-3, 0, 4)          # Get 4 values from 1e-3 to 1e0.
array([ 0.001,  0.01 ,  0.1 ,  1.   ])
```

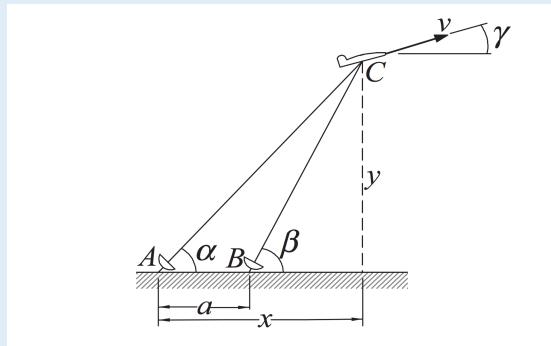

For $x_0 = 1$, your plot should resemble the following figure. Remember to label your plot.

ACHTUNG!

Mathematically, choosing smaller h values results in tighter approximations of $f'(x_0)$. However, Problem 3 shows that when h gets too small, the error stops decreasing. This numerical error is due to the denominator in each finite difference quotient becoming very small. The optimal value of h is usually one that is small, but not too small.

Problem 4. The radar stations A and B , separated by the distance $a = 500$ m, track a plane C by recording the angles α and β at one-second intervals. Your goal, back at air traffic control, is to determine the speed of the plane.^a

Let the position of the plane at time t be given by $(x(t), y(t))$. The speed at time t is the magnitude of the velocity vector, $\|\frac{d}{dt}(x(t), y(t))\| = \sqrt{x'(t)^2 + y'(t)^2}$. The closed forms of the functions $x(t)$ and $y(t)$ are unknown (and may not exist at all), but we can still use numerical methods to estimate $x'(t)$ and $y'(t)$. For example, at $t = 3$, the second order centered difference quotient for $x'(t)$ is

$$x'(3) \approx \frac{x(3+h) - x(3-h)}{2h} = \frac{1}{2}(x(4) - x(2)).$$

In this case $h = 1$ since data comes in from the radar stations at 1 second intervals.

Successive readings for α and β at integer times $t = 7, 8, \dots, 14$ are stored in the file `plane.npy`. Each row in the array represents a different reading; the columns are the observation time t , the angle α (in degrees), and the angle β (also in degrees), in that order. The Cartesian coordinates of the plane can be calculated from the angles α and β as follows.

$$x(\alpha, \beta) = a \frac{\tan(\beta)}{\tan(\beta) - \tan(\alpha)} \quad y(\alpha, \beta) = a \frac{\tan(\beta) \tan(\alpha)}{\tan(\beta) - \tan(\alpha)} \quad (9.4)$$

Load the data, convert α and β to radians, then compute the coordinates $x(t)$ and $y(t)$ at each given t using 9.4. Approximate $x'(t)$ and $y'(t)$ using a first order forward difference quotient for $t = 7$, a first order backward difference quotient for $t = 14$, and a second order centered difference quotient for $t = 8, 9, \dots, 13$ (see Figure 9.1). Return the values of the speed $\sqrt{x'(t)^2 + y'(t)^2}$ at each t as a `np.array`.

(Hint: `np.deg2rad()` will be helpful.)

^aThis problem is adapted from an exercise in [Kiu13].

Numerical Differentiation in Higher Dimensions

Finite difference quotients can also be used to approximate derivatives in higher dimensions. The *Jacobian matrix* of a function $f : \mathbb{R}^n \rightarrow \mathbb{R}^m$ at a point $\mathbf{x}_0 \in \mathbb{R}^n$ is the $m \times n$ matrix J whose entries are given by

$$J_{ij} = \frac{\partial f_i}{\partial x_j}(\mathbf{x}_0).$$

For example, the Jacobian for a function $f : \mathbb{R}^3 \rightarrow \mathbb{R}^2$ is defined by

$$J = \left[\begin{array}{c|c|c} \frac{\partial f_1}{\partial x_1} & \frac{\partial f_1}{\partial x_2} & \frac{\partial f_1}{\partial x_3} \\ \hline \frac{\partial f_2}{\partial x_1} & \frac{\partial f_2}{\partial x_2} & \frac{\partial f_2}{\partial x_3} \end{array} \right] = \left[\begin{array}{ccc} \frac{\partial f_1}{\partial x_1} & \frac{\partial f_1}{\partial x_2} & \frac{\partial f_1}{\partial x_3} \\ \frac{\partial f_2}{\partial x_1} & \frac{\partial f_2}{\partial x_2} & \frac{\partial f_2}{\partial x_3} \end{array} \right], \quad \text{where} \quad f(\mathbf{x}) = \begin{bmatrix} f_1(\mathbf{x}) \\ f_2(\mathbf{x}) \end{bmatrix}, \quad \mathbf{x} = \begin{bmatrix} x_1 \\ x_2 \\ x_3 \end{bmatrix}.$$

The difference quotients in this case resemble directional derivatives. The first order forward difference quotient for approximating a partial derivative is

$$\frac{\partial f}{\partial x_j}(\mathbf{x}_0) \approx \frac{f(\mathbf{x}_0 + h\mathbf{e}_j) - f(\mathbf{x}_0)}{h},$$

where \mathbf{e}_j is the j th standard basis vector. The second order centered difference approximation is

$$\frac{\partial f}{\partial x_j}(\mathbf{x}_0) \approx \frac{f(\mathbf{x}_0 + h\mathbf{e}_j) - f(\mathbf{x}_0 - h\mathbf{e}_j)}{2h}. \quad (9.5)$$

Problem 5. Write a function that accepts a function $f : \mathbb{R}^n \rightarrow \mathbb{R}^m$, a point $\mathbf{x}_0 \in \mathbb{R}^n$, and a float h . Approximate the Jacobian matrix of f at \mathbf{x} using the second order centered difference quotient in (9.5).

(Hint: the standard basis vector \mathbf{e}_j is the j th column of the $n \times n$ identity matrix I .)

To test your function, define a simple function like $f(x, y) = [x^2, x^3 - y]^T$ where the Jacobian is easy to find analytically, then check the results of your function against SymPy or your own scratch work.

Differentiation Software

Many machine learning algorithms and structures, especially neural networks, rely on the gradient of a cost or objective function. To facilitate their research, several organizations have recently developed Python packages for numerical differentiation. For example, the Harvard Intelligent Probabilistic Systems Group (HIPS) started developing `autograd` in 2014 (<https://github.com/HIPS/autograd>) and Google created JAX (<https://github.com/google/jax>) as a successor to `autograd`. Popular deep learning libraries also contain automatic differentiation libraries. These tools use an algorithm known as *automatic differentiation* that is incredibly robust: they can differentiate functions with NumPy routines, `if` statements, `while` loops, and even recursion.

We conclude with a brief introduction to JAX. It can be installed as follows on Mac and Linux:

```
pip install "jax[cpu]"
```

Installation directly via `pip` is currently only supported on Windows *experimentally*. Some unofficial builds for Windows are available at <https://github.com/cloudhan/jax-windows-builder>. JAX also has additional installation options that allow it to do computations on a GPU using the CUDA library. See <https://github.com/google/jax#installation> for additional options for these cases.

JAX's `grad()` accepts a scalar-valued function and returns its gradient as a function that accepts the same parameters as the original. To support most of the NumPy features, JAX comes with its own thinly-wrapped version of Numpy, `jax.numpy`. Import this version of NumPy as `jnp` to avoid confusion.

```
>>> from jax import numpy as jnp          # Use JAX's version of NumPy.
>>> from jax import grad

>>> g = lambda x: jnp.exp(jnp.sin(jnp.cos(x)))
>>> dg = grad(g)                      # dg() is a callable function.
>>> dg(1.)                           # Use floats as input, not ints.
DeviceArray(-1.2069776, dtype=float32, weak_type=True)
```

Functions that `grad()` produces do not support array broadcasting, meaning they do not accept arrays as input. The easiest way to create a function is to use `jnp.vectorize()` on the derivative.

```
>>> pts = jnp.array([1, 2, 3], dtype=float)
>>> dg = jnp.vectorize(grad(g))        # Calculate g'(x) with array support.
>>> dg(pts)                          # Evaluate g'(x) at each of the points.
DeviceArray([-1.2069776, -0.5551414, -0.03356146], dtype=float32)
```

SymPy would have no trouble differentiating $g(x)$ in these examples. However, JAX can also differentiate Python functions that look nothing like traditional mathematical functions. For example, the following code computes the Taylor series of e^x with a loop.

```
>>> from sympy import factorial

>>> def taylor_exp(x, tol=.0001):
...     """Compute the Taylor series of e^x with terms greater than tol."""
...     result, i, term = 0, 0, 1
...     while jnp.abs(term) > tol:
```

```

...
    term = x**i / int(factorial(i))
...
    result, i = result + term, i + 1
...
return result
...
>>> d_exp = grad(taylor_exp)
>>> d_exp(2., .1), d_exp(2., .0001)
(DeviceArray(7.266667, dtype=float32, weak_type=True),
 DeviceArray(7.3889947, dtype=float32, weak_type=True))

```

Problem 6. The *Chebyshev Polynomials* satisfy the recursive relation

$$T_0(x) = 1, \quad T_1(x) = x, \quad T_n(x) = 2xT_{n-1}(x) - T_{n-2}(x).$$

Write a function that accepts an array x and an integer n and recursively computes $T_n(x)$. Use JAX and your first function to create a function for $T'_n(x)$. Use this last function to plot each $T'_n(x)$ over the domain $[-1, 1]$ for $n = 0, 1, 2, 3, 4$.

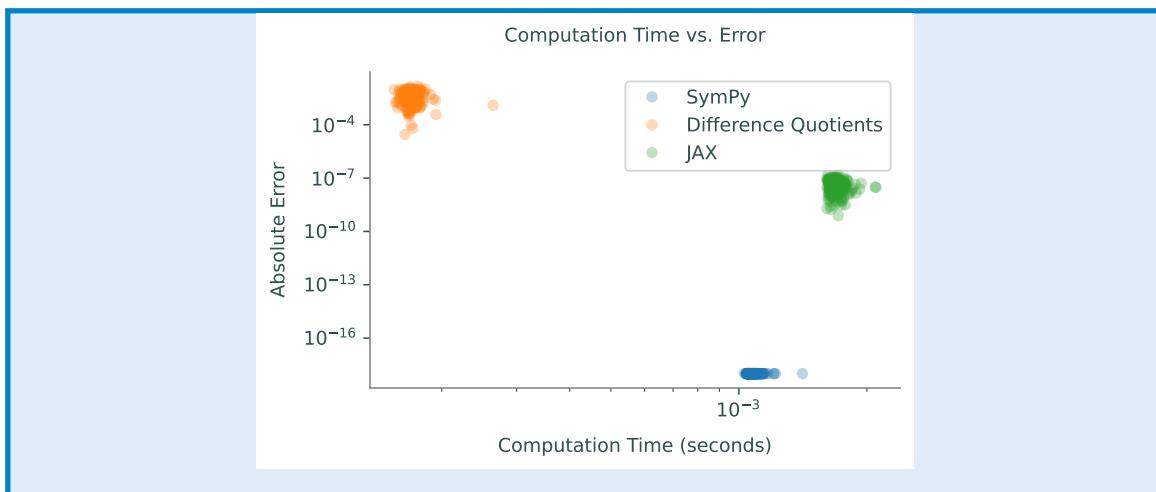

(Hint: Use `jnp.ones_like(x)` to handle the case when $n = 0$.)

Problem 7. Let $f(x) = (\sin(x) + 1)^{\sin(\cos(x))}$ as in Problems 1 and 3. Write a function that accepts an integer N and performs the following experiment N times.

1. Choose a random value x_0 .
2. Use your function from Problem 1 to calculate the “exact” value of $f'(x_0)$. Time how long the entire process takes, including calling your function (each iteration).
3. Time how long it takes to get an approximation $\tilde{f}'(x_0)$ of $f'(x_0)$ using the fourth-order centered difference quotient from Problem 3. Record the absolute error $|f'(x_0) - \tilde{f}'(x_0)|$ of the approximation.
4. Time how long it takes to get an approximation $\bar{f}'(x_0)$ of $f'(x_0)$ using JAX (calling `grad()` every time). Record the absolute error $|f'(x_0) - \bar{f}'(x_0)|$ of the approximation.

Plot the computation times versus the absolute errors on a log-log plot with different colors for SymPy, the difference quotient, and JAX. For SymPy, assume an absolute error of `1e-18` (since only positive values can be shown on a log plot).

For $N = 200$, your plot should resemble the following figure. Note that SymPy has the least error but longer computation time, and that the difference quotient takes the least amount of time but has the most error. JAX, on the other hand, does not appear to be as well-suited to this particular problem. However, for more complicated functions and functions of multiple variables, it tends to be a “happy medium” between the two, with faster runtime than SymPy.

Additional Material

More JAX

For scalar-valued functions with multiple inputs, the parameter `argnums` specifies the variable that the derivative is computed with respect to. Providing a list for `argnums` gives several outputs.

```
>>> f = lambda x, y: 3*x*y + 2*y - x

# Take the derivative of f with respect to the first variable, x.
>>> dfdx = grad(f, argnums=0)           # Should be dfdx(x,y) = 3y - 1,
>>> dfdx(5., 1.)                      # so dfdx(5,1) = 3 - 1 = 2.
DeviceArray(2., dtype=float32, weak_type=True)

# Take the gradient with respect to the second variable, y.
>>> dfdy = grad(f, argnums=1)           # Should be dfdy(x,y) = 3x + 2,
>>> dfdy(5., 1.)                      # so dfdy(5,1) = 15 + 2 = 17.
DeviceArray(17., dtype=float32, weak_type=True)

# Get the full gradient.
>>> grad_f = grad(f, argnums=[0, 1])
>>> jnp.array(grad_f(5., 1.))
DeviceArray([ 2., 17.], dtype=float32)
```

Finally, JAX's `jacobian()` can differentiate vector-valued functions.

```
>>> from jax import jacobian

>>> f = lambda x: jnp.array([x[0]**2, x[0]+x[1]])
>>> f_jac = jacobian(f)
>>> f_jac(jnp.array([1., 1.]))
DeviceArray([[2., 0.],
            [1., 1.]], dtype=float32)
```

10

Conditioning and Stability

Lab Objective: *The condition number of a function measures how sensitive that function is to changes in the input. On the other hand, the stability of an algorithm measures how accurately that algorithm computes the value of a function from exact input. Both of these concepts are important for answering the crucial question, “is my computer telling the truth?” In this lab we examine the conditioning of common linear algebra problems, including computing polynomial roots and matrix eigenvalues. We also present an example to demonstrate how two different algorithms for the same problem may not have the same level of stability.*

Note: There may be some variation in the solutions to problems in this lab between the different updates of NumPy, SciPy, and SymPy. Consider updating these packages if you are currently using older versions.

Conditioning

The *absolute condition number* of a function $f : \mathbb{R}^m \rightarrow \mathbb{R}^n$ at a point $\mathbf{x} \in \mathbb{R}^m$ is defined by

$$\hat{\kappa}(\mathbf{x}) = \lim_{\delta \rightarrow 0^+} \sup_{\|\mathbf{h}\| < \delta} \frac{\|f(\mathbf{x} + \mathbf{h}) - f(\mathbf{x})\|}{\|\mathbf{h}\|}. \quad (10.1)$$

In other words, the absolute condition number of f is the limit of the change in output over the change of input. Similarly, the *relative condition number* of f is the limit of the relative change in output over the relative change in input,

$$\kappa(\mathbf{x}) = \lim_{\delta \rightarrow 0^+} \sup_{\|\mathbf{h}\| < \delta} \left(\frac{\|f(\mathbf{x} + \mathbf{h}) - f(\mathbf{x})\|}{\|f(\mathbf{x})\|} \right) \Bigg/ \frac{\|\mathbf{x}\|}{\|f(\mathbf{x})\|} \hat{\kappa}(\mathbf{x}). \quad (10.2)$$

A function with a large condition number is called *ill-conditioned*. Small changes to the input of an ill-conditioned function may produce large changes in output. It is important to know if a function is ill-conditioned because floating point representation almost always introduces some input error, and therefore the outputs of ill-conditioned functions cannot be trusted.

The *condition number* of a matrix A , $\kappa(A) = \|A\| \|A^{-1}\|$, is an upper bound on the condition number for many of the common problems associated with the matrix, such as solving the system $Ax = b$. If A is square but not invertible, then $\kappa(A) = \infty$ by convention. To compute $\kappa(A)$, we often use the matrix 2-norm, which is the largest singular value σ_{\max} of A . Recall that if σ is a singular value of A , $\frac{1}{\sigma}$ is a singular value of A^{-1} . Thus, we have that

$$\kappa(A) = \frac{\sigma_{\max}}{\sigma_{\min}}, \quad (10.3)$$

which is also a valid equation for non-square matrices.

ACHTUNG!

Ill-conditioned matrices can wreak havoc in even simple applications. For example, the matrix

$$A = \begin{bmatrix} 1 & 1 \\ 1 & 1.0000000001 \end{bmatrix}$$

is extremely ill-conditioned, with $\kappa(A) \approx 4 \times 10^{10}$. Solving the systems $Ax = b_1$ and $Ax = b_2$ can result in wildly different answers, even when b_1 and b_2 are extremely close.

```
>>> import numpy as np
>>> from scipy import linalg as la

>>> A = np.array([[1, 1], [1, 1+1e-10]])
>>> np.linalg.cond(A)
39999991794.058899

# Set up and solve a simple system of equations.
>>> b1 = np.array([2, 2])
>>> x1 = la.solve(A, b1)
>>> print(x1)
[ 2.  0.]

# Solve a system with a very slightly different vector b.
>>> b2 = np.array([2, 2+1e-5])
>>> la.norm(b1 - b2)
>>> x2 = la.solve(A, b2)
>>> print(x2)
[-99997.99172662  99999.99172662] # This solution is hugely different!
```

If you find yourself working with matrices that have large condition numbers, check your math carefully or try to reformulate the problem entirely.

NOTE

An *orthonormal matrix* U has orthonormal columns and satisfies $U^T U = I$ and $\|U\|_2 = 1$. If U is square, then $U^{-1} = U^T$ and U^T is also orthonormal. Therefore $\kappa(U) = \|U\|_2 \|U^{-1}\|_2 = 1$. Even if U is not square, all of its singular values are equal to 1, and again $\kappa(U) = \sigma_{\max}/\sigma_{\min} = 1$.

The condition number of a matrix cannot be less than 1 since $\sigma_{\max} \geq \sigma_{\min}$ by definition. Thus orthonormal matrices are, in a sense, the best kind of matrices for computations. This is one of the main reasons why numerical algorithms based on the QR decomposition or the SVD are so important.

Problem 1. Write a function that accepts a matrix A and computes its condition number using (10.3). Use `scipy.linalg.svd()`, or `scipy.linalg.svdvals()` to compute the singular values of A . Avoid computing A^{-1} . If the smallest singular value is 0, return ∞ (`np.inf`).

Validate your function by comparing it to `np.linalg.cond()`. Check that orthonormal matrices have a condition number of 1 (use `scipy.linalg.qr()` to generate an orthonormal matrix) and that singular matrices have a condition number of ∞ according to your function.

UNIT TEST

The file `test_conditioning_stability.py` contains unit tests to test your function from Problem 1 with orthonormal matrices. There is a place to add your own unit tests to test your function with other kinds of matrices, which will be graded.

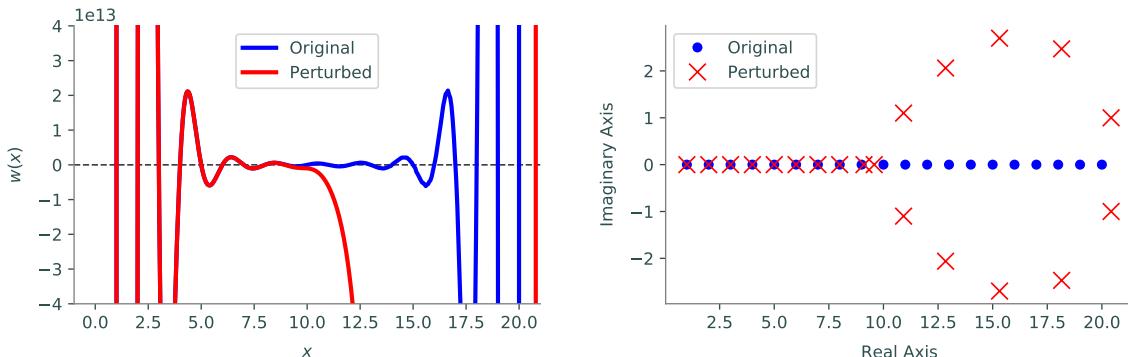

The Wilkinson Polynomial

Let $f : \mathbb{C}^{n+1} \rightarrow \mathbb{C}^n$ be the function that maps a collection of $n + 1$ coefficients $(c_n, c_{n-1}, \dots, c_0)$ to the n roots of the polynomial $c_n x^n + c_{n-1} x^{n-1} + \dots + c_2 x^2 + c_1 x + c_0$. Finding polynomial roots is an extremely ill-conditioned problem in general, so the condition number of f is likely very large. To see this, consider the *Wilkinson polynomial*, made famous by James H. Wilkinson in 1963:

$$w(x) = \prod_{r=1}^{20} (x - r) = x^{20} - 210x^{19} + 20615x^{18} - 1256850x^{17} + \dots$$

Let $\tilde{w}(x)$ be $w(x)$ where the coefficient on x^{19} is very slightly perturbed from -210 to -209.9999999 . The following code computes and compares the roots of $\tilde{w}(x)$ and $w(x)$ using NumPy and SymPy.

Figure 10.1a plots $w(x)$ and $\tilde{w}(x)$ together, and Figure 10.1b and compares their roots in the complex plane.

(a) The original and perturbed Wilkinson polynomials. They match for about half of the domain, then differ drastically.

(b) Roots of the original and perturbed Wilkinson polynomials. About half of the perturbed roots are complex.

Figure 10.1

Figure 10.1 clearly indicates that a very small change in just a single coefficient drastically changes the nature of the polynomial and its roots. To quantify the difference, estimate the condition numbers (this example uses the ∞ norm to compute $\hat{\kappa}$ and κ).

```
>>> import sympy as sy
>>> from matplotlib import pyplot as plt

# The roots of w are 1, 2, ..., 20.
>>> w_roots = np.arange(1, 21)

# Get the exact Wilkinson polynomial coefficients using SymPy.
>>> x, i = sy.symbols('x i')
>>> w = sy.poly_from_expr(sy.product(x-i, (i, 1, 20)))[0]
>>> w_coeffs = np.array(w.all_coeffs())
>>> print(w_coeffs[:6])
[1 -210 20615 -1256850 53327946 -1672280820]

# Perturb one of the coefficients very slightly.
>>> h = np.zeros(21)
>>> h[1]=1e-7
>>> new_coeffs = w_coeffs + h
>>> print(new_coeffs[:6])
[1 -209.99999900000 20615 -1256850 53327946 -1672280820]

# Use NumPy to compute the roots of the perturbed polynomial.
>>> new_roots = np.roots(np.poly1d(new_coeffs))

# Sort the roots to ensure that they are in the same order.
>>> w_roots = np.sort(w_roots)
>>> new_roots = np.sort(new_roots)

# Estimate the absolute condition number in the infinity norm.
```

```
>>> k = la.norm(new_roots - w_roots, np.inf) / la.norm(h, np.inf)
>>> print(k)
27841936.8061

# Estimate the relative condition number in the infinity norm.
>>> k * la.norm(w_coeffs, np.inf) / la.norm(w_roots, np.inf)
1.92161703373792e+25           # This is huge!!
```

There are some caveats to this example.

1. Computing the quotients in (10.1) and (10.2) for a fixed perturbation \mathbf{h} only approximates the condition number. The true condition number is the limit of such quotients. We hope that when $\|\mathbf{h}\|$ is small, a random quotient is at least the same order of magnitude as the limit, but there is no way to be sure.
2. This example assumes that NumPy's root-finding algorithm, `np.roots()`, is *stable*, so that the difference between `w_roots` and `new_roots` is due to the difference in coefficients, and not to problems with `np.roots()`. We will return to this issue in the next section.

Even with these caveats, it is apparent that root finding is a difficult problem to solve correctly. Always check your math carefully when dealing with polynomial roots.

Problem 2. Write a function that carries out the following experiment 100 times.

1. Randomly perturb the true coefficients of the Wilkinson polynomial by replacing each coefficient c_i with $c_i * r_i$, where r_i is drawn from a normal distribution centered at 1 with standard deviation `1e-10` (use `np.random.normal()`).
2. Plot the perturbed roots as small points in the complex plane. That is, plot the real part of the coefficients on the x -axis and the imaginary part on the y -axis. Plot on the same figure in each experiment.
(Hint: use a pixel marker, `marker='.'`, to avoid overcrowding the figure.)
3. Compute the absolute and relative condition numbers with the ∞ norm.

Plot the roots of the unperturbed Wilkinson polynomial with the perturbed roots. Your final plot should resemble Figure 10.2. Finally, return the average computed absolute and relative condition numbers.

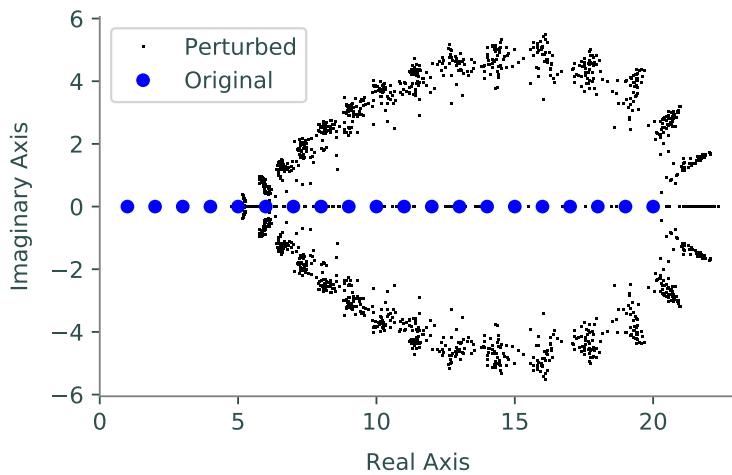

Figure 10.2: This figure replicates Figure 12.1 on p. 93 of [TB97].

Calculating Eigenvalues

Let $f : M_n(\mathbb{C}) \rightarrow \mathbb{C}^n$ be the function that maps an $n \times n$ matrix with complex entries to its n eigenvalues. This problem is well-conditioned for symmetric matrices, but it can be extremely ill-conditioned for non-symmetric matrices. Let A be an $n \times n$ matrix and let λ be the vector of the n eigenvalues of A . If $\tilde{A} = A + H$ is a perturbation of A and $\tilde{\lambda}$ are its eigenvalues, then the condition numbers of f can be estimated by

$$\hat{\kappa}(A) = \frac{\|\lambda - \tilde{\lambda}\|}{\|H\|}, \quad \kappa(A) = \frac{\|A\|}{\|\lambda\|} \hat{\kappa}(A). \quad (10.4)$$

Problem 3. Write a function that accepts a matrix A and estimates the condition number of the eigenvalue problem using (10.4). For the perturbation H , construct a matrix with complex entries where the real and imaginary parts are drawn from normal distributions centered at 0 with standard deviation $\sigma = 10^{-10}$.

```
reals = np.random.normal(0, 1e-10, A.shape)
imags = np.random.normal(0, 1e-10, A.shape)
H = reals + 1j*imags
```

Use `scipy.linalg.eig()` or `scipy.linalg.eigvals()` to compute the eigenvalues of A and $A + H$, and use the 2-norm for both the vector and matrix norms. Return the absolute and relative condition numbers.

The order `scipy.linalg.eig()` and `scipy.linalg.eigvals()` return eigenvalues is completely arbitrary, which means that the eigenvalues of A and $A+H$ may be returned in different orders. Without correcting for this, the computed value of $\|\lambda - \tilde{\lambda}\|$ can be very large even if the two matrices have very similar eigenvalues. Additionally, `np.sort()` does not help, as many matrices have sets of eigenvalues for which the sort order of this function is itself ill-conditioned. So, before comparing the two lists of eigenvalues, use the following function to reorder both to be as close as possible to each other:

```
def reorder_eigvals(orig_eigvals, pert_eigvals):
    """Reorder the perturbed eigenvalues to be as close to the original ←
        eigenvalues as possible.

    Parameters:
        orig_eigvals ((n,) ndarray) - The eigenvalues of the unperturbed ←
            matrix A
        pert_eigvals ((n,) ndarray) - The eigenvalues of the perturbed ←
            matrix A+H

    Returns:
        ((n,) ndarray) - the reordered eigenvalues of the perturbed matrix
    """

    n = len(pert_eigvals)
    sort_order = np.zeros(n).astype(int)
    dists = np.abs(orig_eigvals - pert_eigvals.reshape(-1, 1))
    for _ in range(n):
        index = np.unravel_index(np.argmin(dists), dists.shape)
        sort_order[index[0]] = index[1]
        dists[index[0], :] = np.inf
        dists[:, index[1]] = np.inf
    return pert_eigvals[sort_order]
```

Problem 4. Write a function that accepts bounds $[x_{\min}, x_{\max}, y_{\min}, y_{\max}]$ and an integer `res`. Use your function from Problem 3 to compute the relative condition number of the eigenvalue problem for the 2×2 matrix

$$\begin{bmatrix} 1 & x \\ y & 1 \end{bmatrix}$$

at every point of an evenly spaced `res` \times `res` grid over the domain $[x_{\min}, x_{\max}] \times [y_{\min}, y_{\max}]$. Plot these estimated relative condition numbers using `plt.pcolormesh()` and the colormap `cmap='gray_r'` (you can use `plt.colorbar()` to create the colorbar). With `res=200`, your plot should look similar to the following figure.

Problem 4 shows that the conditioning of the eigenvalue problem depends heavily on the matrix, and that it is difficult to know a priori how bad the problem will be. Luckily, most real-world problems requiring eigenvalues are symmetric. Trefethen famously summed up the issue of conditioning and eigenvalues when he said, “if the answer is highly sensitive to perturbations, you have probably asked the wrong question” [Tre98].

Stability

The *stability* of an algorithm is measured by the error in its output. Let $f : \mathbb{R}^m \rightarrow \mathbb{R}^n$ be a problem to be solved, as in the previous section, and let \tilde{f} be an actual algorithm for solving the problem. The *forward error* of f at \mathbf{x} is $\|f(\mathbf{x}) - \tilde{f}(\mathbf{x})\|$, and the *relative forward error* of f at \mathbf{x} is

$$\frac{\|f(\mathbf{x}) - \tilde{f}(\mathbf{x})\|}{\|f(\mathbf{x})\|}.$$

An algorithm is called *stable* if its relative forward error is small.¹

As an example, consider again NumPy’s root-finding algorithm that we used to investigate the Wilkinson polynomial. The exact roots of $w(x)$ are clearly $1, 2, \dots, 20$. Had we not known this, we could have tried computing the roots from the coefficients using `np.roots()` (without perturbing the coefficients at all).

```
# w_coeffs holds the coefficients and w_roots holds the true roots.
>>> computed_roots = np.sort(np.roots(np.poly1d(w_coeffs)))
>>> print(computed_roots[:6])      # The computed roots are close to integers.
[ 1.                2.                3.                3.99999999  5.00000076  5.99998749]

# Compute the forward error.
>>> forward_error = la.norm(w_roots - computed_roots)
>>> print(forward_error)
0.020612653126379665
```

¹See the Additional Material section for alternative (and more rigorous) definitions of algorithmic stability.

```
# Compute the relative forward error.
>>> forward_error / la.norm(w_roots)
0.00038476268486104599 # The error is nice and small.
```

This analysis suggests that `np.roots()` is a stable algorithm, so large condition numbers of Problem 2 really are due to the poor conditioning of the problem, not the way in which the problem was solved.

NOTE

Conditioning is a property of a **problem** to be solved, such as finding the roots of a polynomial or calculating eigenvalues. Stability is a property of an **algorithm** to solve a problem, such as `np.roots()` or `scipy.linalg.eig()`. If a problem is ill-conditioned, any algorithm used to solve that problem may result in suspicious solutions, even if that algorithm is stable.

Least Squares

The *ordinary least squares* (OLS) problem is to find the \mathbf{x} that minimizes $\|A\mathbf{x} - \mathbf{b}\|_2$ for fixed A and \mathbf{b} . It can be shown that an equivalent problem is finding the solution of $A^H A \mathbf{x} = A^H \mathbf{b}$, called the *normal equations*. A common application of least squares is polynomial approximation. Given a set of m data points $\{(x_k, y_k)\}_{k=1}^m$, the goal is to find the set of coefficients $\{c_i\}_{i=0}^n$ such that

$$y_k \approx c_n x_k^n + c_{n-1} x_k^{n-1} + \cdots + c_2 x_k^2 + c_1 x_k + c_0$$

for all k , with the smallest possible error. These m linear equations yield the linear system

$$A\mathbf{x} = \begin{bmatrix} x_1^n & x_1^{n-1} & \cdots & x_1^2 & x_1 & 1 \\ x_2^n & x_2^{n-1} & \cdots & x_2^2 & x_2 & 1 \\ x_3^n & x_3^{n-1} & \cdots & x_3^2 & x_3 & 1 \\ \vdots & \vdots & & \vdots & \vdots & \vdots \\ x_m^n & x_m^{n-1} & \cdots & x_m^2 & x_m & 1 \end{bmatrix} \begin{bmatrix} c_n \\ c_{n-1} \\ \vdots \\ c_2 \\ c_1 \\ c_0 \end{bmatrix} = \begin{bmatrix} y_1 \\ y_2 \\ y_3 \\ \vdots \\ y_m \end{bmatrix} = \mathbf{b}. \quad (10.5)$$

Problem 5. Write a function that accepts an integer n . Solve for the coefficients of the polynomial of degree n that best fits the data found in `stability_data.npy`. Use two approaches to get the least squares solution:

1. Use `la.inv()` to solve the normal equations: $\mathbf{x} = (A^T A)^{-1} A^T \mathbf{b}$. Although this approach seems intuitive, it is actually highly unstable and can return an answer with a very large forward error.
2. Use `la.qr()` with `mode='economic'` and `la.solve_triangular()` to solve the system $R\mathbf{x} = Q^T \mathbf{b}$, which is equivalent to solving the normal equations. This algorithm has the advantage of being stable.

Load the data and set up the system (10.5) with the following code.

```
xk, yk = np.load("stability_data.npy").T
A = np.vander(xk, n+1)
```

Plot the resulting polynomials together with the raw data points. Return the forward error $\|Ax - b\|_2$ of both approximations.

(Hint: The function `np.polyval()` will be helpful for plotting the resulting polynomials.)

Test your function using various values of n , taking special note of what happens for values of n near 14.

Catastrophic Cancellation

When a computer takes the difference of two very similar numbers, the result is often stored with a small number of significant digits and the tiniest bit of information is lost. However, these small errors can propagate into large errors later down the line. This phenomenon is called *catastrophic cancellation*, and is a common cause for numerical instability.

Catastrophic cancellation is a potential problem whenever floats or large integers that are very close to one another are subtracted. This problem can be avoided by either rewriting the program to not use subtraction, or by increasing the number of significant digits that the computer tracks.

For example, consider the simple problem of computing $\sqrt{a} - \sqrt{b}$. The computation can be done directly with subtraction, or by performing the equivalent division

$$\sqrt{a} - \sqrt{b} = (\sqrt{a} - \sqrt{b}) \frac{\sqrt{a} + \sqrt{b}}{\sqrt{a} + \sqrt{b}} = \frac{a - b}{\sqrt{a} + \sqrt{b}}.$$

```
>>> from math import sqrt          # np.sqrt() fails for very large numbers.

>>> a = 10**20 + 1
>>> b = 10**20
>>> sqrt(a) - sqrt(b)           # Do the subtraction directly.
0.0                            # a != b, so information has been lost.

>>> (a - b) / (sqrt(a) + sqrt(b))  # Use the alternative formulation.
5e-11                           # Much better!
```

In this example, a and b are distinct enough that the computer can still tell that $a - b = 1$, but \sqrt{a} and \sqrt{b} are so close to each other that $\sqrt{a} - \sqrt{b}$ is computed as 0.

Problem 6. Let $I(n) = \int_0^1 x^n e^{x-1} dx$. It can be shown that for a positive integer n ,

$$I(n) = (-1)^n (!n - \frac{n!}{e}), \quad (10.6)$$

where $!n = n! \sum_{k=0}^n \frac{(-1)^k}{k!}$ is the *subfactorial* of n . Write a function to do the following.

1. Use SymPy's `sy.integrate()` to evaluate the integral form of $I(n)$ for $n = 5, 10, \dots, 50$. Convert the symbolic results of each integration to a float. Since this is done symbolically, these values can be accepted as the true values of $I(n)$. For this problem, use `sy.exp()` in the integrand.
(Hint: be careful that the values of n in the integrand are of type `int`.)
2. Use (10.6) to compute $I(n)$ for the same values of n . Use `sy.subfactorial()` to compute $!n$ and `sy.factorial()` to compute $n!$. The function used for e in this equation changes the returned error value. For this problem, use `np.e` instead of `sy.exp()`.
(Hint: be careful to only pass Python integers to these functions.)
3. Plot the relative forward error of the results computed in step 2 at each of the given values of n . When computing the relative forward error use absolute values instead of `la.norm()`. Use a log scale on the y -axis.

The examples presented in this lab are just a few of the ways that a mathematical problem can turn into a computational train wreck. Always use stable algorithms when possible, and remember to check if problems are well conditioned or not.

Additional Material

Other Notions of Stability

The definition of stability can be made more rigorous in the following way. Let f be a problem to solve and \tilde{f} an algorithm to solve it. If for every \mathbf{x} in the domain there exists a $\tilde{\mathbf{x}}$ such that

$$\frac{\|\tilde{\mathbf{x}} - \mathbf{x}\|}{\|\mathbf{x}\|} \quad \text{and} \quad \frac{\|\tilde{f}(\mathbf{x}) - f(\tilde{\mathbf{x}})\|}{\|f(\tilde{\mathbf{x}})\|}$$

are small (close to $\epsilon_{\text{machine}} \approx 10^{-16}$), then \tilde{f} is called stable. In other words, “A stable algorithm gives nearly the right answer to nearly the right question” [TB97, p.104]. Note carefully that the quantity on the right is slightly different from the plain forward error introduced earlier.

Stability is desirable, but plain stability isn’t the best possible condition. For example, if for every input \mathbf{x} there exists a $\tilde{\mathbf{x}}$ such that $\|\tilde{\mathbf{x}} - \mathbf{x}\|/\|\mathbf{x}\|$ is small and $\tilde{f}(\mathbf{x}) = f(\tilde{\mathbf{x}})$ exactly, then \tilde{f} is called *backward stable*. Thus “A backward stable algorithm gives exactly the right answer to nearly the right question” (Trefethen, Bao, 104). Backward stable algorithms are generally more trustworthy than stable algorithms, but they are also less common.

Stability of Linear System Solvers

The algorithms presented so far in this manual have different levels of stability. The LU decomposition (with pivoting) is usually very good, but there are some pathological examples of matrices that can cause it to break down. Even so, `scipy.linalg.solve()` uses the LU decomposition. The QR decomposition (also with pivoting) is generally considered to be a better option than the LU decomposition and is more stable. However, solving a linear system using the SVD is even more stable than using the QR decomposition. For this reason, `scipy.linalg.lstsq()` uses the SVD.

11

Monte Carlo Integration

Lab Objective: *Many important integrals cannot be evaluated symbolically because the integrand has no antiderivative. Traditional numerical integration techniques like Newton-Cotes formulas and Gaussian quadrature usually work well for one-dimensional integrals, but rapidly become inefficient in higher dimensions. Monte Carlo integration is an integration strategy that has relatively slow convergence, but that does extremely well in high-dimensional settings compared to other techniques. In this lab we implement Monte Carlo integration and apply it to a classic problem in statistics.*

Volume Estimation

Since the area of a circle of radius r is $A = \pi r^2$, one way to numerically estimate π is to compute the area of the unit circle. Empirically, we can estimate the area by randomly choosing points in a domain that encompasses the unit circle. The percentage of points that land within the unit circle approximates the percentage of the area of the domain that the unit circle occupies. Multiplying this percentage by the total area of the sample domain gives an estimate for the area of the circle.

Since the unit circle has radius $r = 1$, consider the square domain $\Omega = [-1, 1] \times [-1, 1]$. The following code samples 2000 uniformly distributed random points in Ω , determines what percentage of those points are within the unit circle, then multiplies that percentage by 4 (the area of Ω) to get an estimate for π .

```
>>> import numpy as np
>>> from scipy import linalg as la

# Get 2000 random points in the 2-D domain [-1, 1]x[-1, 1].
>>> points = np.random.uniform(-1, 1, (2, 2000))

# Determine how many points are within the circle.
>>> lengths = la.norm(points, axis=0)
>>> num_within = np.count_nonzero(lengths < 1)

# Estimate the circle's area.
>>> 4 * (num_within / 2000)
3.198
```

The estimate $\pi \approx 3.198$ isn't perfect, but it only differs from the true value of π by about 0.0564. On average, increasing the number of sample points decreases the estimate error.

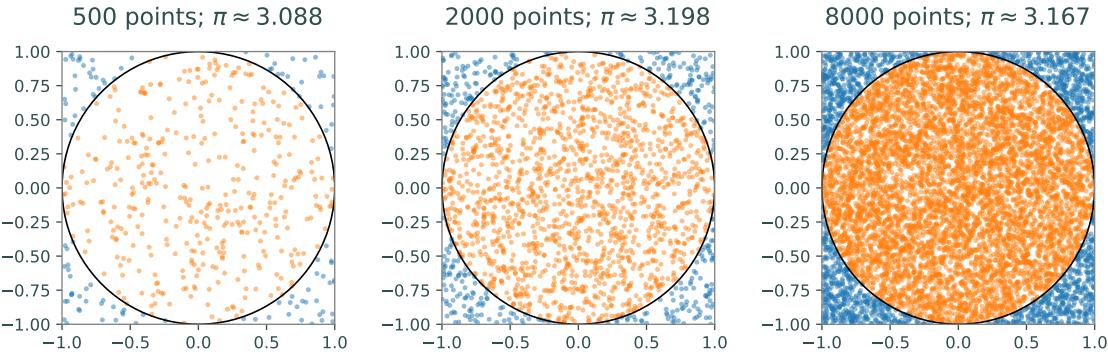

Figure 11.1: Estimating the area of the unit circle using random points.

Problem 1. The n -dimensional *open unit ball* is the set $U_n = \{\mathbf{x} \in \mathbb{R}^n \mid \|\mathbf{x}\|_2 < 1\}$. Write a function that accepts an integer n and a keyword argument N defaulting to 10^4 . Estimate the volume of U_n by drawing N points over the n -dimensional domain $[-1, 1] \times [-1, 1] \times \cdots \times [-1, 1]$. (Hint: the volume of $[-1, 1] \times [-1, 1] \times \cdots \times [-1, 1]$ is 2^n .)

When $n = 2$, this is the same experiment outlined above so your function should return an approximation of π . The volume of the U_3 is $\frac{4}{3}\pi \approx 4.18879$, and the volume of U_4 is $\frac{\pi^2}{2} \approx 4.9348$. Try increasing the number of sample points N to see if your estimates improve.

Integral Estimation

The strategy for estimating π can be formulated as an integral problem. Define $f : \mathbb{R}^2 \rightarrow \mathbb{R}$ by

$$f(\mathbf{x}) = \begin{cases} 1 & \text{if } \|\mathbf{x}\|_2 < 1 \text{ (\mathbf{x} is within the unit circle)} \\ 0 & \text{otherwise,} \end{cases}$$

and let $\Omega = [-1, 1] \times [-1, 1]$ as before. Then

$$\int_{-1}^1 \int_{-1}^1 f(x, y) dx dy = \int_{\Omega} f(\mathbf{x}) dV = \pi.$$

To estimate the integral we chose N random points $\{\mathbf{x}_i\}_{i=1}^N$ in Ω . Since f indicates whether or not a point lies within the unit circle, the total number of random points that lie in the circle is the sum of the $f(\mathbf{x}_i)$. Then the average of these values, multiplied by the volume $V(\Omega)$, is the desired estimate:

$$\int_{\Omega} f(\mathbf{x}) dV \approx V(\Omega) \frac{1}{N} \sum_{i=1}^N f(\mathbf{x}_i). \quad (11.1)$$

This remarkably simple equation can be used to estimate the integral of any integrable function $f : \mathbb{R}^n \rightarrow \mathbb{R}$ over any domain $\Omega \subset \mathbb{R}^n$ and is called the general formula for *Monte Carlo integration*.

The intuition behind (11.1) is that $\frac{1}{N} \sum_{i=1}^N f(\mathbf{x}_i)$ approximates the average value of f on Ω , and multiplying the approximate average value by the volume of Ω yields the approximate integral of f over Ω . This is a little easier to see in one dimension: for a single-variable function $f : \mathbb{R} \rightarrow \mathbb{R}$, the Average Value Theorem states that the average value of f over an interval $[a, b]$ is given by

$$f_{avg} = \frac{1}{b-a} \int_a^b f(x) dx.$$

Then using the approximation $f_{avg} \approx \frac{1}{N} \sum_{i=1}^N f(x_i)$, the previous equation becomes

$$\int_a^b f(x) dx = (b-a)f_{avg} \approx V(\Omega) \frac{1}{N} \sum_{i=1}^N f(x_i), \quad (11.2)$$

which is (11.1) in one dimension. In this setting $\Omega = [a, b]$ and hence $V(\Omega) = b - a$.

Problem 2. Write a function that accepts a function $f : \mathbb{R} \rightarrow \mathbb{R}$, bounds of integration a and b , and an integer N defaulting to 10^4 . Use `np.random.uniform()` to sample N points over the interval $[a, b]$, then use (11.2) to estimate the integral

$$\int_a^b f(x) dx.$$

Test your function on the following integrals, or on other integrals that you can check by hand.

$$\begin{aligned} \int_{-4}^2 x^2 dx &= 24 & \int_{-2\pi}^{2\pi} \sin(x) dx &= 0 & \int_1^{10} \frac{1}{x} dx &= \log(10) \approx 2.30259 \\ \int_1^5 |\sin(10x) \cos(10x) + \sqrt{x} \sin(3x)| dx &\approx 4.502 \end{aligned}$$

ACHTUNG!

Be careful not to use Monte Carlo integration to estimate integrals that do not converge. For example, since $1/x$ approaches ∞ as x approaches 0 from the right, the integral

$$\int_0^1 \frac{1}{x} dx$$

does not converge. Even so, attempts at Monte Carlo integration still return a finite value. Use various numbers of sample points to see whether or not the integral estimate is converging.

```
>>> for N in [5000, 7500, 10000]:
...     print(np.mean(1. / np.random.uniform(0, 1, N)), end='\t')
...
11.8451683722    25.5814419888    7.64364735049    # No convergence.
```

Integration in Higher Dimensions

The implementation of (11.1) for a function $f : \mathbb{R}^n \rightarrow \mathbb{R}$ with $n > 1$ introduces a few tricky details, but the overall procedure is the same for the case when $n = 1$. We consider only the case where $\Omega \subset \mathbb{R}^n$ is an n -dimensional box $[a_1, b_1] \times [a_2, b_2] \times \cdots \times [a_n, b_n]$.

1. If $n = 1$ then Ω is a line, so $V(\Omega) = b_1 - a_1$. If $n = 2$ then Ω is a rectangle, and hence $V(\Omega) = (b_1 - a_1)(b_2 - a_2)$, the product of the side lengths. The volume of a higher-dimensional box Ω is also the product of the side lengths,

$$V(\Omega) = \prod_{i=1}^n (b_i - a_i) \quad (11.3)$$

2. It is easy to sample uniformly over an interval $[a, b]$ with `np.random.uniform()`, or even over the n -dimensional cube $[a, b] \times [a, b] \times \cdots \times [a, b]$ (such as in Problem 1). However, if $a_i \neq a_j$ or $b_i \neq b_j$ for any $i \neq j$, the samples need to be constructed in a slightly different way.

The interval $[0, 1]$ can be transformed to the interval $[a, b]$ by scaling it so that it is the same length as $[a, b]$, then shifting it to the appropriate location.

$$[0, 1] \xrightarrow{\text{scale by } b-a} [0, b-a] \xrightarrow{\text{shift by } a} [a, b]$$

This suggests a strategy for sampling over $[a_1, b_1] \times [a_2, b_2] \times \cdots \times [a_n, b_n]$: sample uniformly from the n -dimensional box $[0, 1] \times [0, 1] \times \cdots \times [0, 1]$, multiply the i th component of each sample by $b_i - a_i$, then add a_i to that component.

$$[0, 1] \times \cdots \times [0, 1] \xrightarrow{\text{scale}} [0, b_1 - a_1] \times \cdots \times [0, b_n - a_n] \xrightarrow{\text{shift}} [a_1, b_1] \times \cdots \times [a_n, b_n] \quad (11.4)$$

Problem 3. Write a function that accepts a function $f : \mathbb{R}^n \rightarrow \mathbb{R}$, a list of lower bounds $[a_1, a_2, \dots, a_n]$, a list of upper bounds $[b_1, b_2, \dots, b_n]$, and an integer N defaulting to 10^4 . Use (11.1), (11.3), and (11.4) with N sample points to estimate the integral

$$\int_{\Omega} f(\mathbf{x}) dV,$$

where $\Omega = [a_1, b_1] \times [a_2, b_2] \times \cdots \times [a_n, b_n]$. Return your answer as a float.

(Hint: use a list comprehension to calculate all of the $f(\mathbf{x}_i)$ quickly.)

Test your function on the following integrals below, as well as the single dimensional examples from Problem 2.

(Hint: make sure bounds are inputted as lists, even in the single dimensional case).

$$\begin{aligned} \int_0^1 \int_0^1 x^2 + y^2 dx dy &= \frac{2}{3} & \int_{-2}^1 \int_1^3 3x - 4y + y^2 dx dy &= 54 \\ \int_{-4}^4 \int_{-3}^3 \int_{-2}^2 \int_{-1}^1 x + y - wz^2 dx dy dz dw &= 0 \end{aligned}$$

Note carefully how the order of integration defines the domain; in the last example, the x - y - z - w domain is $[-1, 1] \times [-2, 2] \times [-3, 3] \times [-4, 4]$, so the lower and upper bounds passed to your function should be $[-1, -2, -3, -4]$ and $[1, 2, 3, 4]$, respectively.

Convergence

Monte Carlo integration has some obvious pros and cons. On the one hand, it is difficult to get highly precise estimates. In fact, the error of the Monte Carlo method is proportional to $1/\sqrt{N}$, where N is the number of points used in the estimation. This means that dividing the error by 10 requires using 100 times more sample points.

On the other hand, the convergence rate is independent of the number of dimensions of the problem. That is, the error converges at the same rate whether integrating a 2-dimensional function or a 20-dimensional function. This gives Monte Carlo integration a huge advantage over other methods, and makes it especially useful for estimating integrals in high dimensions where other methods become computationally infeasible.

Problem 4. The probability density function of the joint distribution of n independent normal random variables, each with mean 0 and variance 1, is the function $f : \mathbb{R}^n \rightarrow \mathbb{R}$ defined by

$$f(\mathbf{x}) = \frac{1}{(2\pi)^{n/2}} e^{-\frac{\|\mathbf{x}\|^2}{2}}.$$

Though this is a critical distribution in statistics, f does not have a symbolic antiderivative.

Integrate f several times to study the convergence properties of Monte Carlo integration.

- Let $n = 4$ and $\Omega = [-\frac{3}{2}, \frac{3}{4}] \times [0, 1] \times [0, \frac{1}{2}] \times [0, 1] \subset \mathbb{R}^4$. Define f and Ω so that you can integrate f over Ω using your function from Problem 3.
 - Use `scipy.stats.multivariate_normal.cdf()` to compute what we will call the “exact” value of $F = \int_{\Omega} f(\mathbf{x}) dV$. As an example, the following code computes the integral over $[-1, 1] \times [-1, 3] \times [-2, 1] \subset \mathbb{R}^3$.

3. Use `np.logspace()` to get 20 **integer** values of N that are roughly logarithmically spaced from 10^1 to 10^5 . For each value of N , use your function from Problem 3 to compute an estimate $\tilde{F}(N)$ of the integral with N samples. Compute the relative error $\frac{|F - \tilde{F}(N)|}{|F|}$ for each value of N .
4. Plot the relative error against the sample size N on a log-log scale. Also plot the line $1/\sqrt{N}$ for comparison. Your results should be similar to Figure 11.2.

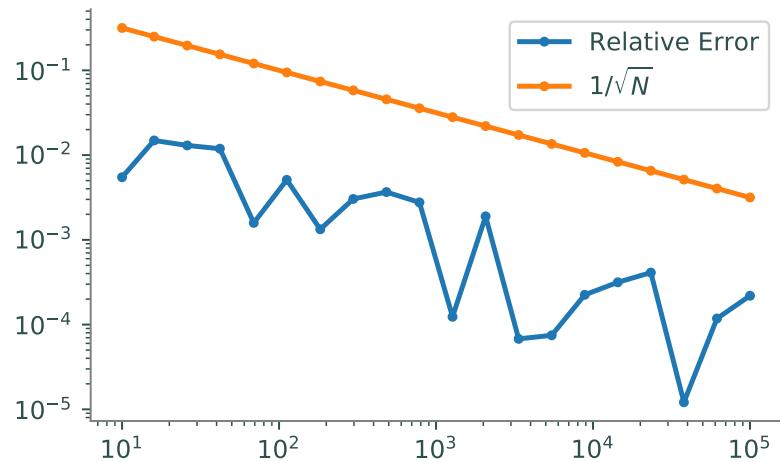

Figure 11.2: Monte Carlo integration converges at the same rate as $1/\sqrt{N}$ where N is the number of samples used in the estimate. However, the convergence is independent of dimension, which is why this strategy is so commonly used for high-dimensional integration.

12

Visualizing Complex-valued Functions

Lab Objective: *Functions that map from the complex plane into the complex plane are difficult to fully visualize because the domain and range are both 2-dimensional. However, such functions can be visualized at the expense of partial information. In this lab we present methods for analyzing complex-valued functions visually, including locating their zeros and poles in the complex plane. We recommend completing the exercises in a Jupyter Notebook.*

Representations of Complex Numbers

A complex number $z = x + iy$ can be written in *polar coordinates* as $z = re^{i\theta}$ where

- $r = |z| = \sqrt{x^2 + y^2}$ is the *magnitude* of z , and
- $\theta = \arg(z) = \arctan(y/x)$ is the *argument* of z , the angle in radians between z and 0.

Conversely, Euler's formula is the relation $re^{i\theta} = r \cos(\theta) + ir \sin(\theta)$. Then setting $re^{i\theta} = x + iy$ and equating real and imaginary parts yields the equations $x = r \cos(\theta)$ and $y = r \sin(\theta)$.

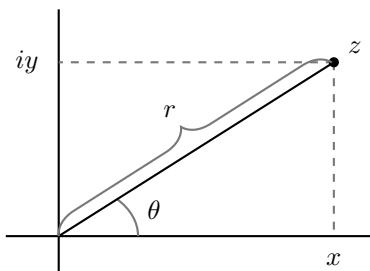

Figure 12.1: The complex number z can be represented in Cartesian coordinates as $z = x + iy$ and in polar coordinates as $z = re^{i\theta}$, when θ is in radians.

NumPy makes it easy to work with complex numbers and convert between coordinate systems. The function `np.angle()` returns the argument θ of a complex number (between $-\pi$ and π) and `np.abs()` (or `np.absolute()`) returns the magnitude r . These functions also operate element-wise on NumPy arrays.

```

>>> import numpy as np

>>> z = 2 - 2*j                      # 1j is the imaginary unit i = sqrt(-1).
>>> r, theta = np.abs(z), np.angle(z)
>>> print(r, theta)                  # The angle is between -pi and pi.
2.82842712475 -0.785398163397

# Check that z = r * e^(i*theta)
>>> np.isclose(z, r*np.exp(1j*theta))
True

# These function also work on entire arrays.
>>> np.abs(np.arange(5) + 2j*np.arange(5))
array([ 0.          ,  2.23606798,  4.47213595,  6.70820393,  8.94427191])

```

Complex Functions

A function $f : \mathbb{C} \rightarrow \mathbb{C}$ is called a *complex-valued function*. Visualizing f is difficult because \mathbb{C} has 2 real dimensions, so the graph of f should be 4-dimensional. However, since it is possible to visualize 3-dimensional objects, f can be visualized by ignoring one dimension. There are two main strategies for doing this: assign a color to each point $z \in \mathbb{C}$ corresponding to either the argument θ of $f(z)$, or to the magnitude r of $f(z)$. The graph that uses the argument is called a *complex color wheel graph*. Figure 12.2 displays the identity function $f(z) = z$ using these two methods.

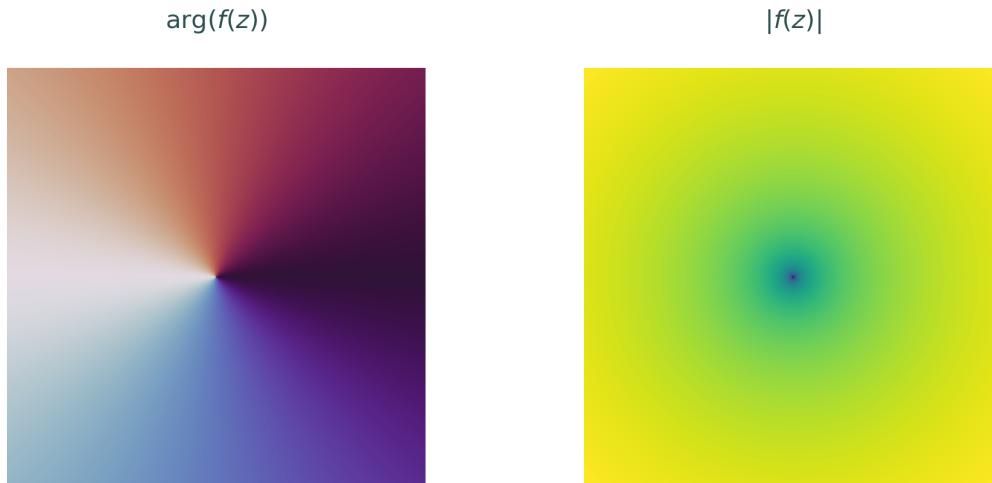

Figure 12.2: The identity function $f : \mathbb{C} \rightarrow \mathbb{C}$ defined by $f(z) = z$. On the left, the color at each point z represents the angle $\theta = \arg(f(z))$. As θ goes from $-\pi$ to π , the colors cycle smoothly counterclockwise from white to blue to red and back to white (this colormap is called "[twilight](#)"). On the right, the color represents the magnitude $r = |f(z)|$. The further a point is from the origin, the greater its magnitude (the colormap is the default, "[viridis](#)").

The plots in Figure 12.2 use Cartesian coordinates in the domain and polar coordinates in the codomain. The procedure for plotting in this way is fairly simple. Begin by creating a grid of complex numbers: create the real and imaginary parts separately, then use `np.meshgrid()` to turn them into a single array of complex numbers. Pass this array to the function f , compute the angle and argument of the resulting array, and plot them using `plt.pcolormesh()`. The following code sets up the complex domain grid.

```
>>> x = np.linspace(-1, 1, 400)      # Real domain.
>>> y = np.linspace(-1, 1, 400)      # Imaginary domain.
>>> X, Y = np.meshgrid(x, y)        # Make grid matrices.
>>> Z = X + 1j*Y                  # Combine the grids into a complex array.
```

Visualizing the argument and the magnitude separately provides different perspectives of the function f . The angle plot is generally more useful for visualizing function behavior, though the magnitude plot often makes it easy to spot important points such as zeros and poles.

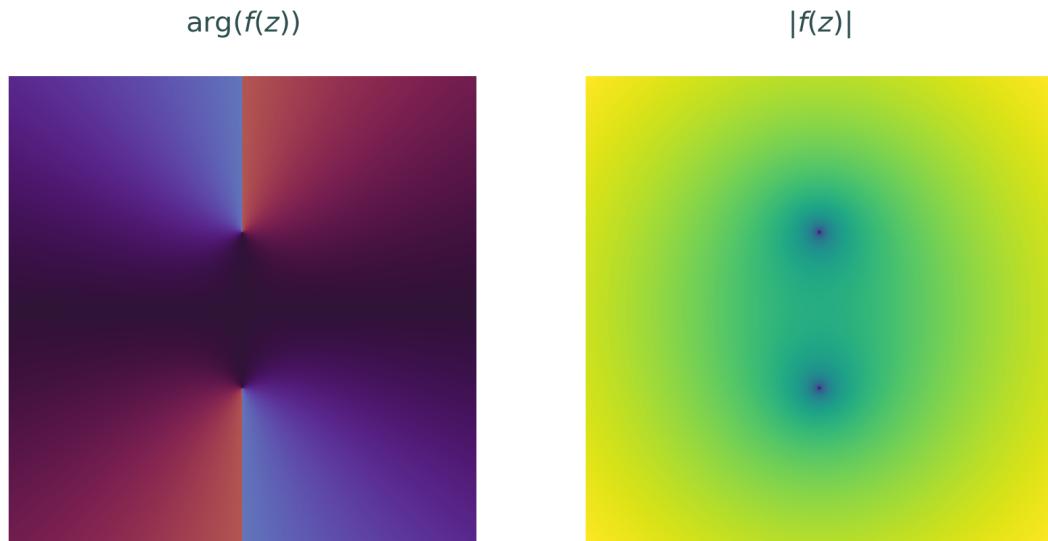

Figure 12.3: Plots of $f(z) = \sqrt{z^2 + 1}$ on $\{x+iy \mid x, y \in [-3, 3]\}$. Notice how a discontinuity is clearly visible in the angle plot on the left, but disappears from the magnitude plot on the right.

Problem 1. Write a function that accepts a function $f : \mathbb{C} \rightarrow \mathbb{C}$, bounds $[r_{\min}, r_{\max}, i_{\min}, i_{\max}]$ for the domain, an integer `res` that determines the resolution of the plot, and a string to set the figure title. Plot $\arg(f(z))$ and $|f(z)|$ on an equally-spaced `res`×`res` grid over the domain $\{x+iy \mid x \in [r_{\min}, r_{\max}], y \in [i_{\min}, i_{\max}]\}$ in separate subplots.

1. For $\arg(f(z))$, set the `plt.pcolormesh()` keyword arguments `vmin` and `vmax` to $-\pi$ and π , respectively. This forces the color spectrum to work well with `np.angle()`. Use the colormap "`twilight`", which starts and ends white, so that the color is the same for $-\pi$ and π .

2. For $|f(z)|$, set `norm=matplotlib.colors.LogNorm()` in `plt.pcolormesh()` so that the color scale is logarithmic. Use a sequential colormap like "`viridis`" or "`magma`".
3. Set the aspect ratio to "`equal`" in each plot. Give each subplot a title, and set the overall figure title with the given input string.

Use your function to visualize $f(z) = z$ on $\{x + iy \mid x, y \in [-1, 1]\}$ and $f(z) = \sqrt{z^2 + 1}$ on $\{x + iy \mid x, y \in [-3, 3]\}$. Compare the resulting plots to Figures 12.2 and 12.3, respectively.

Interpreting Complex Plots

Plots of a complex function can be used to quickly identify important points in the function's domain.

Zeros

A complex number z_0 is called a *zero* of the complex-valued function f if $f(z_0) = 0$. The *multiplicity* or *order* of z_0 is the largest integer n such that f can be written as $f(z) = (z - z_0)^n g(z)$ where $g(z_0) \neq 0$. In other words, f has a zero of order n at z_0 if the Taylor series of f centered at z_0 can be written as

$$f(z) = \sum_{k=n}^{\infty} a_k (z - z_0)^k, \quad a_n \neq 0.$$

Angle and magnitude plots make it easy to locate a function's zeros and to determine their multiplicities.

Problem 2. Use your function from Problem 1 to plot the following functions on the domain $\{x + iy \mid x, y \in [-1, 1]\}$.

- $f(z) = z^n$ for $n = 2, 3, 4$.
- $f(z) = z^3 - iz^4 - 3z^6$. Compare the resulting plots to Figure 12.4.

Use a Markdown cell to write a sentence or two about how the zeros of a function and their multiplicity appear in angle and magnitude plots.

Problem 2 shows that in an angle plot of $f(z) = z^n$, the colors cycle n times counterclockwise around 0. This is explained by looking at z^n in polar coordinates,

$$z^n = (re^{i\theta})^n = r^n e^{i(n\theta)}.$$

Multiplying θ by a number greater than 1 compresses the graph along the “ θ -axis” by a factor of n . In other words, the output angle repeats itself n times in one cycle of θ . This is similar to taking a scalar-valued function $f : \mathbb{R} \rightarrow \mathbb{R}$ and replacing $f(x)$ with $f(nx)$.

Problem 2 also shows that the plot of $f(z) = z^3 - iz^4 - 3z^6$ looks very similar to the plot of $f(z) = z^3$ near the origin. This is because when z is close to the origin, z^4 and z^6 are much smaller in magnitude than z^3 , and so the behavior of z^3 dominates the function. In terms of the Taylor series centered at $z_0 = 0$, the quantity $|z - z_0|^{n+k}$ is much smaller than $|z - z_0|^n$ for z close to z_0 , and so the function behaves similar to $a_n(z - z_0)^n$.

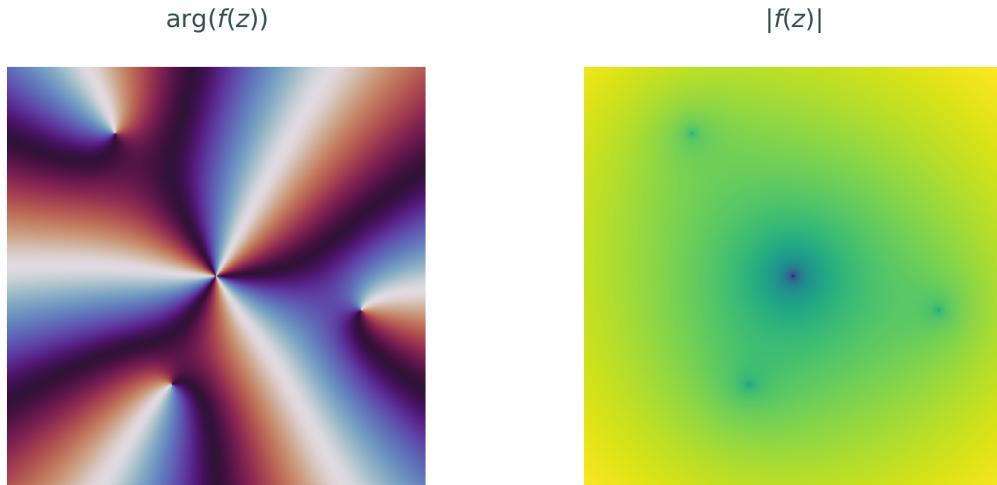

Figure 12.4: The angle plot of $f(z) = z^3 - iz^4 - 3z^6$ on $\{x + iy \mid x, y \in [-1, 1]\}$. The angle plot shows that $f(z)$ has a zero of order 3 at the origin and 3 distinct zeros of order 1 scattered around the origin. The magnitude plot makes it easier to pinpoint the location of the zeros.

Poles

A complex number z_0 is called a *pole* of the complex-valued function f if f can be written as $f(z) = g(z)/(z - z_0)$ where $g(z_0) \neq 0$. From this definition it is easy to see that $\lim_{z \rightarrow z_0} |f(z)| = \infty$, but knowing that $\lim_{z \rightarrow z_1} |f(z)| = \infty$ is not enough information to conclude that z_1 is a pole of f .

The *order* of z_0 is the largest integer n such that f can be written as $f(z) = g(z)/(z - z_0)^n$ with $g(z_0) \neq 0$. In other words, f has a pole of order n at z_0 if its Laurent series on a punctured neighborhood of z_0 can be written as

$$f(z) = \sum_{k=-n}^{\infty} a_k (z - z_0)^k \quad , a_{-n} \neq 0.$$

Problem 3. Plot the following functions on domains that show all of its zeros and/or poles.

- $f(z) = z^{-n}$ for $n = 1, 2, 3$.
- $f(z) = z^2 + iz^{-1} + z^{-3}$.

Use a Markdown cell to write a sentence or two about how the poles of a function appear in angle and magnitude plots. How can you tell the multiplicity of the poles from the plot?

Problem 3 shows that in angle plot of z^{-1} , the colors cycle n times clockwise around 0, as opposed to the counter-clockwise rotations seen around roots. Again, this can be explained by looking at the polar representation,

$$z^{-n} = (re^{i\theta})^{-n} = r^{-n}e^{i(-n\theta)}.$$

The minus sign on the θ reverses the direction of the colors, and the n makes them cycle n times.

From Problem 3 it is also clear that $f(z) = z^2 + iz^{-1} + z^{-3}$ behaves similarly to z^{-3} for z near the pole at $z_0 = 0$. Since $|z - z_0|^{-n+k}$ is much smaller than $|z - z_0|^{-n}$ when $|z - z_0|$ is small, near z_0 the function behaves like $a_{-n}(z - z_0)^{-n}$. This is why the order of a pole can be estimated by counting the number of times the colors circle a point in the clockwise direction.

Counting Zeros and Poles

The *Fundamental Theorem of Algebra* states that a polynomial f with highest degree n has exactly n zeros, counting multiplicity. For example, $f(z) = z^2 + 1$ has two zeros, and $f(z) = (z - i)^3$ has three zeros, all at $z_0 = i$ (that is, $z_0 = i$ is a zero with multiplicity 3).

The number of poles of function can also be apparent if it can be written as a quotient of polynomials. For example, $f(z) = z/(z+i)(z-i)^2$ has one zeros and three poles, counting multiplicity.

Problem 4. Plot the following functions and count the number and order of their zeros and poles. Adjust the bounds of each plot until you have found all zeros and poles.

- $f(z) = -4z^5 + 2z^4 - 2z^3 - 4z^2 + 4z - 4$
- $f(z) = z^7 + 6z^6 - 131z^5 - 419z^4 + 4906z^3 - 131z^2 - 420z + 4900$
- $f(z) = \frac{16z^4+32z^3+32z^2+16z+4}{16z^4-16z^3+5z^2}$

It is usually fairly easy to see how many zeros or poles a polynomial or quotient of polynomials has. However, it can be much more difficult to know how many zeros or poles a different function may or may not have without visualizing it.

Problem 5. Plot the following functions on the domain $\{x + iy \mid x, y \in [-8, 8]\}$. Explain carefully in a Markdown cell what each graph reveals about the function and why the function behaves that way.

- $f(z) = e^z$
- $f(z) = \tan(z)$

(Hint: use the polar coordinate representation to mathematically examine the magnitude and angle of each function.)

Essential Poles

A complex-valued function f has an *essential pole* at z_0 if its Laurent series in a punctured neighborhood of z_0 requires infinitely many terms with negative exponents. For example,

$$e^{1/z} = \sum_{k=0}^{\infty} \frac{1}{n!z^n} = 1 + \frac{1}{z} + \frac{1}{2}\frac{1}{z^2} + \frac{1}{6}\frac{1}{z^3} + \dots$$

An essential pole can be thought of as a pole of order ∞ . Therefore, in an angle plot the colors cycle infinitely many times around an essential pole.

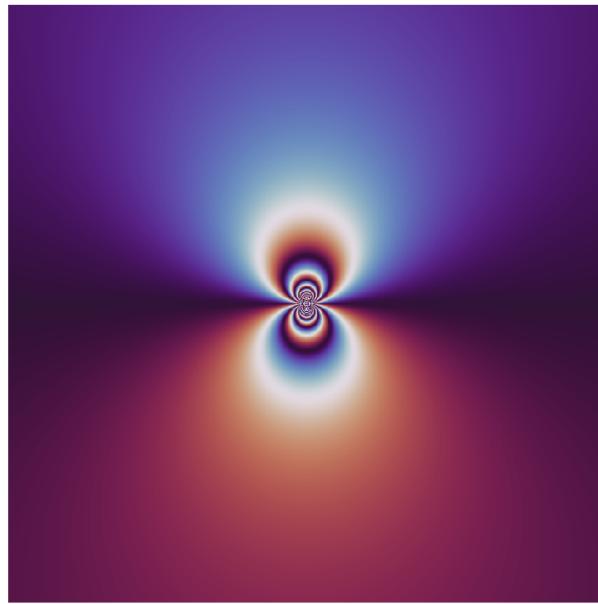

Figure 12.5: Angle plot of $f(z) = e^{1/z}$ on the domain $\{x + iy \mid x, y \in [-1, 1]\}$. The colors circle clockwise around the origin because it is a pole, not a zero. Because the pole is essential, the colors repeat infinitely many times.

ACHTUNG!

Often, color plots like the ones presented in this lab can be deceptive because of a bad choice of domain. Be careful to validate your observations mathematically.

Problem 6. For each of the following functions, plot the function on $\{x + iy \mid x, y \in [-1, 1]\}$ and describe what this view of the plot seems to imply about the function. Then plot the function on a domain that allows you to see the true nature of the roots and poles and describe how it is different from what the original plot implied. Use Markdown cells to write your answers.

- $f(z) = 100z^2 + z$
- $f(z) = \sin\left(\frac{1}{100z}\right)$.

(Hint: zoom way in.)

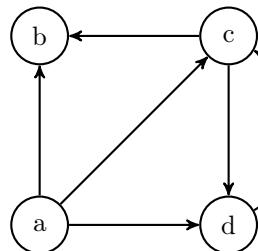

13

The PageRank Algorithm

Lab Objective: Many real-world systems—the internet, transportation grids, social media, and so on—can be represented as graphs (networks). The PageRank algorithm is one way of ranking the nodes in a graph by importance. Though it is a relatively simple algorithm, the idea gave birth to the Google search engine in 1998 and has shaped much of the information age since then. In this lab we implement the PageRank algorithm with a few different approaches, then use it to rank the nodes of a few different networks.

The PageRank Model

The internet is a collection of webpages, each of which may have a hyperlink to any other page. One possible model for a set of n webpages is a directed graph, where each node represents a page and node j points to node i if page j links to page i . The corresponding *adjacency matrix* A satisfies $A_{ij} = 1$ if node j links to node i and $A_{ij} = 0$ otherwise.

$$A = \begin{matrix} & \begin{matrix} a & b & c & d \end{matrix} \\ \begin{matrix} a \\ b \\ c \\ d \end{matrix} & \left[\begin{matrix} 0 & 0 & 0 & 0 \\ 1 & 0 & 1 & 0 \\ 1 & 0 & 0 & 1 \\ 1 & 0 & 1 & 0 \end{matrix} \right] \end{matrix}$$

Figure 13.1: A directed unweighted graph with four nodes, together with its adjacency matrix. Note that the column for node b is all zeros, indicating that b is a *sink*—a node that doesn’t point to any other node.

If n users start on random pages in the network and click on a link every 5 minutes, which page in the network will have the most views after an hour? Which will have the fewest? The goal of the PageRank algorithm is to solve this problem in general, therefore determining how “important” each webpage is.

Before diving into the mathematics, there is a potential problem with the model. What happens if a webpage doesn't have any outgoing links, like node b in Figure 13.1? Eventually, all of the users will end up on page b and be stuck there forever. To obtain a more realistic model, modify each sink in the graph by adding edges from the sink to every node in the graph. This means users on a page with no links can start over by selecting a random webpage.

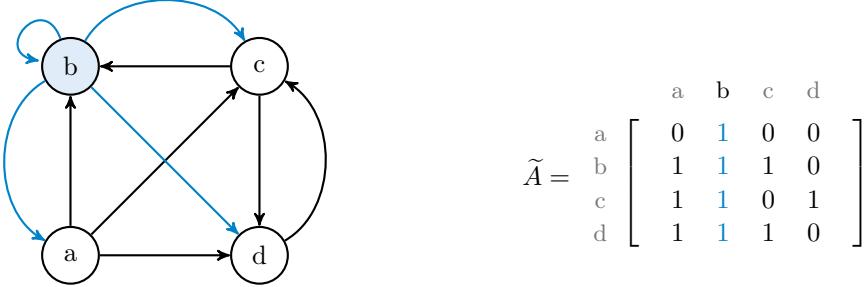

Figure 13.2: Here the graph in Figure 13.1 has been modified to guarantee that node b is no longer a sink (the added links are blue). We denote the modified adjacency matrix by \tilde{A} .

Now let $p_k(t)$ be the likelihood that a particular internet user is surfing webpage k at time t . Suppose at time $t+1$, the user clicks on a link to page i . Then $p_i(t+1)$ can be computed by counting the number of links pointing to page i , weighted by the total number of outgoing links for each node.

As an example, consider the graph in Figure 13.2. To get to page a at time $t+1$, the user had to be on page b at time t . Since there are four outgoing links from page b, assuming links are chosen with equal likelihood,

$$p_a(t+1) = \frac{1}{4}p_b(t).$$

Similarly, to get to page b at time $t+1$, the user had to have been on page a, b, or c at time t . Since a has 3 outgoing edges, b has 4 outgoing edges, and c has 2 outgoing edges,

$$p_b(t+1) = \frac{1}{3}p_a(t) + \frac{1}{4}p_b(t) + \frac{1}{2}p_c(t).$$

The previous equations can be written in a way that hints at a more general linear form:

$$\begin{aligned} p_a(t+1) &= 0p_a(t) + \frac{1}{4}p_b(t) + 0p_c(t) + 0p_d(t), \\ p_b(t+1) &= \frac{1}{3}p_a(t) + \frac{1}{4}p_b(t) + \frac{1}{2}p_c(t) + 0p_d(t). \end{aligned}$$

The coefficients of the terms on the right hand side are precisely the entries of the i th row of the modified adjacency matrix \tilde{A} , divided by the j th column sum. In general, $p_i(t+1)$ satisfies

$$p_i(t+1) = \sum_{j=1}^n \tilde{A}_{ij} \frac{p_j(t)}{\sum_{k=1}^n \tilde{A}_{kj}}. \quad (13.1)$$

Note that the column sum $\sum_{k=1}^n \tilde{A}_{kj}$ in the denominator can never be zero since, after the fix in Figure 13.2, none of the nodes in the graph are sinks.

Accounting for Boredom

The model in (13.1) assumes that the user can only click on links from their current page. It is more realistic to assume that the user sometimes gets bored and randomly picks a new starting page. Let $0 \leq \varepsilon \leq 1$, called the *damping factor*, be the probability that a user stays interested at step t . Then the probability that the user gets bored at any time (and then chooses a new random page) is $1 - \varepsilon$, and (13.1) becomes

$$p_i(t+1) = \underbrace{\varepsilon \sum_{j=1}^n \left(\tilde{A}_{ij} \frac{p_j(t)}{\sum_{k=1}^n \tilde{A}_{kj}} \right)}_{\text{User stayed interested and clicked a link on the current page}} + \underbrace{\frac{1-\varepsilon}{n}}_{\text{User got bored and chose a random page}}. \quad (13.2)$$

Note that (13.2) can be rewritten as the matrix equation

$$\mathbf{p}(t+1) = \varepsilon \hat{A} \mathbf{p}(t) + \frac{1-\varepsilon}{n} \mathbf{1}, \quad (13.3)$$

where $\mathbf{p}(t) = [p_1(t), p_2(t), \dots, p_n(t)]^\top$, $\mathbf{1}$ is a vector of n ones, and \hat{A} is the $n \times n$ matrix with entries

$$\hat{A}_{ij} = \frac{\tilde{A}_{ij}}{\sum_{k=1}^n \tilde{A}_{kj}}. \quad (13.4)$$

In other words, \hat{A} is \tilde{A} normalized so that the columns each sum to 1. For the graph in Figure 13.2, the matrix \hat{A} is given by

$$\hat{A} = \begin{matrix} & \text{a} & \text{b} & \text{c} & \text{d} \\ \text{a} & 0 & 1/4 & 0 & 0 \\ \text{b} & 1/3 & 1/4 & 1/2 & 0 \\ \text{c} & 1/3 & 1/4 & 0 & 1 \\ \text{d} & 1/3 & 1/4 & 1/2 & 0 \end{matrix}. \quad (13.5)$$

Problem 1. Write a class for representing directed graphs via their adjacency matrices. The constructor should accept an $n \times n$ adjacency matrix A and a list of node labels (such as `[a, b, c, d]`) defaulting to `None`. Modify A as in Figure 13.2 so that there are no sinks in the corresponding graph, then calculate the \hat{A} from (13.4). Save \hat{A} and the list of labels as attributes. Use $[0, 1, \dots, n - 1]$ as the labels if none are provided. Finally, raise a `ValueError` if the number of labels is not equal to the number of nodes in the graph.
(Hint: use array broadcasting to compute \hat{A} efficiently.)

For the graph in Figure 13.1, check that your \hat{A} matches (13.5).

ACHTUNG!

The values of the matrix A are often integers, while the values of \hat{A} are generally floats. NumPy can cause issues when attempting to add floats to an integer matrix, so be sure to convert A to a matrix of floats before calculating \hat{A} .

Computing the Rankings

In the model (13.2), define the *rank* of node i as the limit

$$p_i = \lim_{t \rightarrow \infty} p_i(t).$$

There are several ways to solve for $\mathbf{p} = \lim_{t \rightarrow \infty} \mathbf{p}(t)$.

Linear System

If \mathbf{p} exists, then taking the limit as $t \rightarrow \infty$ to both sides of (13.3) gives the following.

$$\begin{aligned} \lim_{t \rightarrow \infty} \mathbf{p}(t+1) &= \lim_{t \rightarrow \infty} \left[\varepsilon \hat{A} \mathbf{p}(t) + \frac{1-\varepsilon}{n} \mathbf{1} \right] \\ \mathbf{p} &= \varepsilon \hat{A} \mathbf{p} + \frac{1-\varepsilon}{n} \mathbf{1} \\ (I - \varepsilon \hat{A}) \mathbf{p} &= \frac{1-\varepsilon}{n} \mathbf{1} \end{aligned} \tag{13.6}$$

This linear system is easy to solve as long as the number of nodes in the graph isn't too large.

Eigenvalue Problem

Let E be an $n \times n$ matrix of ones. Then $E\mathbf{p}(t) = \mathbf{1}$ since $\sum_{i=1}^n p_i(t) = 1$. Substituting into (13.3),

$$\mathbf{p}(t+1) = \varepsilon \hat{A} \mathbf{p}(t) + \frac{1-\varepsilon}{n} E \mathbf{p}(t) = \left(\varepsilon \hat{A} + \frac{1-\varepsilon}{n} E \right) \mathbf{p}(t) = B \mathbf{p}(t), \tag{13.7}$$

where $B = \varepsilon \hat{A} + \frac{1-\varepsilon}{n} E$. Now taking the limit at $t \rightarrow \infty$ of both sides of (13.7),

$$B \mathbf{p} = \mathbf{p}.$$

That is, \mathbf{p} is an eigenvector of B corresponding to the eigenvalue $\lambda = 1$. In fact, since the columns of B sum to 1, and because the entries of B are strictly positive (because the entries of E are all positive), Perron's theorem guarantees that $\lambda = 1$ is the unique eigenvalue of B of largest magnitude, and that the corresponding eigenvector \mathbf{p} is unique up to scaling. Furthermore, \mathbf{p} can be scaled so that each of its entries are positive, meaning $\mathbf{p}/\|\mathbf{p}\|_1$ is the desired PageRank vector.

NOTE

A *Markov chain* is a weighted directed graph where each node represents a *state* of a discrete system. The weight of the edge from node j to node i is the probability of transitioning from state j to state i , and the adjacency matrix of a Markov chain is called a *transition matrix*.

Since B from (13.7) contains nonnegative entries and its columns all sum to 1, it can be viewed as the transition matrix of a Markov chain. In that context, the limit vector \mathbf{p} is called the *steady state* of the Markov chain.

Iterative Method

Solving (13.6) or (13.7) is feasible for small networks, but they are not efficient strategies for very large systems. The remaining option is to use an iterative technique. Starting with an initial guess $\mathbf{p}(0)$, use (13.3) to compute $\mathbf{p}(1), \mathbf{p}(2), \dots$ until $\|\mathbf{p}(t) - \mathbf{p}(t-1)\|$ is sufficiently small. From (13.7), we can see that this is just the power method¹ for finding the eigenvector corresponding to the dominant eigenvalue of B .

Problem 2. Add the following methods to your class from Problem 1. Each should accept a damping factor ε (defaulting to 0.85), compute the PageRank vector \mathbf{p} , and return a dictionary mapping label i to its PageRank value p_i .

1. `linsolve()`: solve for \mathbf{p} in (13.6).
2. `eigensolve()`: solve for \mathbf{p} using (13.7). Normalize the resulting eigenvector so its entries sum to 1. Your answer should be a real number, so use `.real` to constrain the sum to the reals (it might try to have an imaginary part equal to 0).
3. `itersolve()`: in addition to ε , accept an integer `maxiter` and a float `tol`. Iterate on (13.3) until $\|\mathbf{p}(t) - \mathbf{p}(t-1)\|_1 < \text{tol}$ or $t > \text{maxiter}$. Use $\mathbf{p}(0) = [\frac{1}{n}, \frac{1}{n}, \dots, \frac{1}{n}]^T$ as the initial vector (any positive vector that sums to 1 will do, but this assumes equal starting probabilities).

Check that each method yields the same results. For the graph in Figure 13.1 with $\varepsilon = 0.85$, you should get the following dictionary mapping labels to PageRank values.

```
{'a': 0.095758635, 'b': 0.274158285, 'c': 0.355924792, 'd': 0.274158285}
```

UNIT TEST

The file `test_pagerank.py` contains a prewritten unit test to test your `linsolve()` method for Problem 2. There is a place for you to add unit tests to test your other two methods for Problem 2, `eigensolve()` and `itersolve()`, which will be graded.

Problem 3. Write a function that accepts a dictionary mapping labels to PageRank values, like the outputs in Problem 2. Return a list of labels sorted **from highest to lowest** rank. (Hint: if d is a dictionary, use `list(d.keys())` and `list(d.values())` to get the list of keys and values in the dictionary, respectively.)

For the graph in Figure 13.1 with $\varepsilon = 0.85$, this is the list [c, b, d, a] (or [c, d, b, a], since b and d have the same PageRank value).

¹See the Least Squares and Computing Eigenvalues lab for details on the power method.

Problem 4. The file `web_stanford.txt` contains information on Stanford University webpages^a and the hyperlinks between them, gathered in 2002.^b Each line of the file is formatted as `a/b/c/d/e/f...`, meaning the webpage with ID `a` has hyperlinks to webpages with IDs `b`, `c`, `d`, and so on.

Write a function that accepts a damping factor ε defaulting to 0.85. Read the data and get a list of the n unique page IDs in the file (the labels). Construct the $n \times n$ adjacency matrix of the graph where node j points to node i if webpage j has a hyperlink to webpage i . Use your class from Problem 1 and its `itersolve()` method from Problem 2 to compute the PageRank values of the webpages, then rank them with your function from Problem 3. In the case where two webpages have the same rank, resolve ties by first listing the webpage whose ID comes first alphabetically. Note that even though the IDs are numbers, we can sort them alphabetically because they are defined as strings. (Hint: Sorting the list of unique webpage IDs by string before ranking them will place the site IDs in the desired order; there is no need to convert the IDs to integers.) Return the ranked list of webpage IDs.

(Hint: After constructing the list of webpage IDs, make a dictionary that maps a webpage ID to its index in the list. For Figure 13.1, this would be `{'a': 0, 'b': 1, 'c': 2, 'd': 3}`. The values are the row/column indices in the adjacency matrix for each label.)

With $\varepsilon = 0.85$, the top three ranked webpage IDs are 98595, 32791, and 28392.

^a<http://www.stanford.edu/>

^bSee <http://snap.stanford.edu/data/web-Stanford.html> for the original (larger) dataset.

PageRank on Weighted Graphs

Nothing in the formulation of the PageRank model (13.3) requires that the edges of the graph are unweighted. If A_{ij} is the weight of the edge from node j to node i (weight 0 meaning there is no edge from j to i), then the columns of \widehat{A} still sum to 1. Thus $B = \varepsilon\widehat{A} + \frac{1-\varepsilon}{n}E$ is still positive definite, so we can expect a unique PageRank vector \mathbf{p} to exist.

Adding weights to the edges can improve the fidelity of the model and produce a slightly more realistic PageRank ordering. On a given webpage, for example, if hyperlinks to page a are clicked on more frequently than hyperlinks to page b , the edge from node a should be given more weight than the edge to node b .

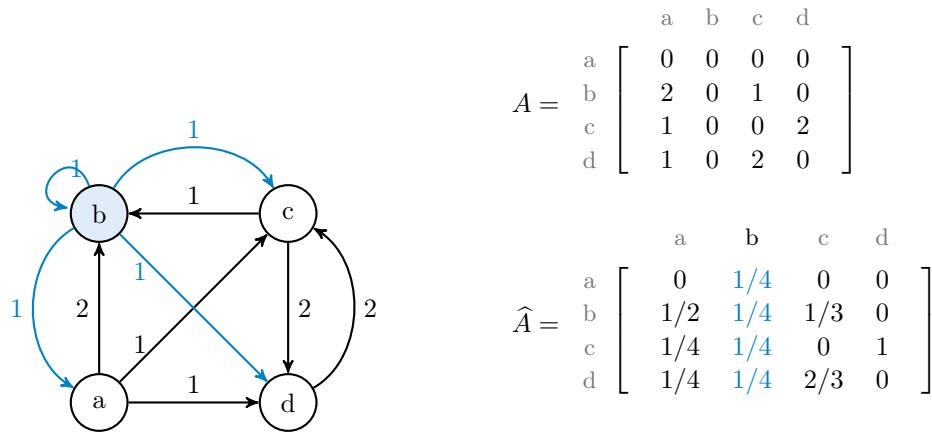

Figure 13.3: A directed weighted graph with four nodes, together with its adjacency matrix and the corresponding PageRank transition matrix. Edges that are added to fix sinks have weight 1, so the computation of \hat{A} and \hat{A} are exactly the same as in Figure 13.2 and (13.4), respectively.

Problem 5. The files `ncaa2010.csv`, `ncaa2011.csv`, ..., `ncaa2017.csv` each contain data for men's college basketball for a given school year.^a Each line (except the very first line, which is a header) represents a different basketball game, formatted `winning_team,losing_team`.

Write a function that accepts a filename and a damping factor ε defaulting to 0.85. Read the specified file (skipping the first line) and get a list of the n unique teams in the file. Construct the $n \times n$ adjacency matrix of the graph where node j points to node i with weight w if team j was defeated by team i in w games. That is, **edges point from losers to winners**. For instance, the graph in Figure 13.3 would indicate that team c lost to team b once and to team d twice, team b was undefeated, and team a never won a game. Use your class from Problem 1 and its `itersolve()` method from Problem 2 to compute the PageRank values of the teams, then rank them with your function from Problem 3. Return the ranked list of team names.

Using `ncaa2010.csv` with $\varepsilon = 0.85$, the top three ranked teams (of the 607 total teams) should be UConn, Kentucky, and Louisville, in that order. That season, UConn won the championship, Kentucky was a semifinalist, and Louisville lost in the first tournament round (a surprising upset).

^a`ncaa2010.csv` has data for the 2010–2011 season, `ncaa2011.csv` for the 2011–2012 season, and so on.

NOTE

In Problem 5, the damping factor ε acts as an “upset” factor: a larger ε puts more emphasis on win history; a smaller ε allows more randomness in the system, giving underdog teams a higher probability of defeating a team with a better record.

It is also worth noting that the sink-fixing procedure is still reasonable for this model because it gives every other team **equal** likelihood of beating an undefeated team. That is, the additional edges don't provide an extra advantage to any one team.

PageRank with NetworkX

NetworkX, usually imported as `nx`, is a third-party package for working with networks. It represents graphs internally with dictionaries, thus taking full advantage of the sparsity in a graph. The base class for directed graphs is called `nx.DiGraph`. Nodes and edges are usually added or removed incrementally with the following methods.

Method	Description
<code>add_node()</code>	Add a single node.
<code>add_nodes_from()</code>	Add a list of nodes.
<code>add_edge()</code>	Add an edge between two nodes, adding the nodes if needed.
<code>add_edges_from()</code>	Add multiple edges (and corresponding nodes as needed).
<code>remove_edge()</code>	Remove a single edge (no nodes are removed).
<code>remove_edges_from()</code>	Remove multiple edges (no nodes are removed).
<code>remove_node()</code>	Remove a single node and all adjacent edges.
<code>remove_nodes_from()</code>	Remove multiple nodes and all adjacent edges.

Table 13.1: Methods of the `nx.DiGraph` class for inserting or removing nodes and edges.

For example, the weighted graph in Figure 13.3 can be constructed with the following code.

```
>>> import networkx as nx

# Initialize an empty directed graph.
>>> DG = nx.DiGraph()

# Add the directed edges (nodes are added automatically).
>>> DG.add_edge('a', 'b', weight=2)      # a --> b (adds nodes a and b)
>>> DG.add_edge('a', 'c', weight=1)      # a --> c (adds node c)
>>> DG.add_edge('a', 'd', weight=1)      # a --> d (adds node d)
>>> DG.add_edge('c', 'b', weight=1)      # c --> b
>>> DG.add_edge('c', 'd', weight=2)      # c --> d
>>> DG.add_edge('d', 'c', weight=2)      # d --> c
```

Once constructed, an `nx.Digraph` object can be queried for information about the nodes and edges. It also supports dictionary-like indexing to access node and edge attributes, such as the weight of an edge.

Method	Description
<code>has_node(A)</code>	Return <code>True</code> if A is a node in the graph.
<code>has_edge(A,B)</code>	Return <code>True</code> if there is an edge from A to B.
<code>edges()</code>	Iterate through the edges.
<code>nodes()</code>	Iterate through the nodes.
<code>number_of_nodes()</code>	Return the number of nodes.
<code>number_of_edges()</code>	Return the number of edges.

Table 13.2: Methods of the `nx.DiGraph` class for accessing nodes and edges.

```
# Check the nodes and edges.
>>> DG.has_node('a')
True
>>> DG.has_edge('b', 'a')
False
>>> list(DG.nodes())
['a', 'b', 'c', 'd']
>>> list(DG.edges())
[('a', 'b'), ('a', 'c'), ('a', 'd'), ('c', 'b'), ('c', 'd'), ('d', 'c')]

# Change the weight of the edge (a, b) to 3.
>>> DG['a']['b']["weight"] += 1
>>> DG['a']['b']["weight"]
3
```

NetworkX efficiently implements several graph algorithms. The function `nx.pagerank()` computes the PageRank values of each node iteratively with sparse matrix operations. This function returns a dictionary mapping nodes to PageRank values, like the methods in Problem 2.

```
# Calculate the PageRank values of the graph.
>>> nx.pagerank(DG, alpha=0.85)      # alpha is the damping factor (epsilon).
{'a': 0.08767781186947843,
 'b': 0.23613138394239835,
 'c': 0.3661321209576019,
 'd': 0.31005868323052127}
```

ACHTUNG!

NetworkX also has a class, `nx.Graph`, for *undirected graphs*. The edges in an undirected graph are bidirectional, so the corresponding adjacency matrix is symmetric.

The PageRank algorithm is not very useful for undirected graphs. In fact, the PageRank value for node is close to its *degree*—the number of edges it connects to—divided by the total number of edges. In Problem 5, that would mean the team who simply played the most games would be ranked the highest. Always use `nx.DiGraph`, not `nx.Graph`, for PageRank and other algorithms that rely on directed edges.

Problem 6. The file `top250movies.txt` contains data from the 250 top-rated movies according to IMDb.^a Each line in the file lists a movie title and its cast as `title/actor1/actor2/...`, with the actors listed mostly in billing order (stars first), though some casts are listed alphabetically or in order of appearance.

Create a `nx.DiGraph` object with a node for each actor in the file. The weight from actor a to actor b should be the number of times that actor a and b were in a movie together but actor b was listed first. That is, **edges point to higher-billed actors** (see Figure 13.4). Compute the PageRank values of the actors and use your function from Problem 3 to rank them. Return the list of ranked actors.

(Hint: Consider using `itertools.combinations()` while constructing the graph. Also, use `encoding="utf-8"` as an argument to `open()` to read the file, since several actors and actresses have nonstandard characters in their names such as ϕ and æ .)

With $\varepsilon = 0.7$, the top three actors should be Leonardo DiCaprio, Robert De Niro, and Tom Hanks, in that order.

^ahttps://www.imdb.com/search/title?groups=top_250&sort=user_rating

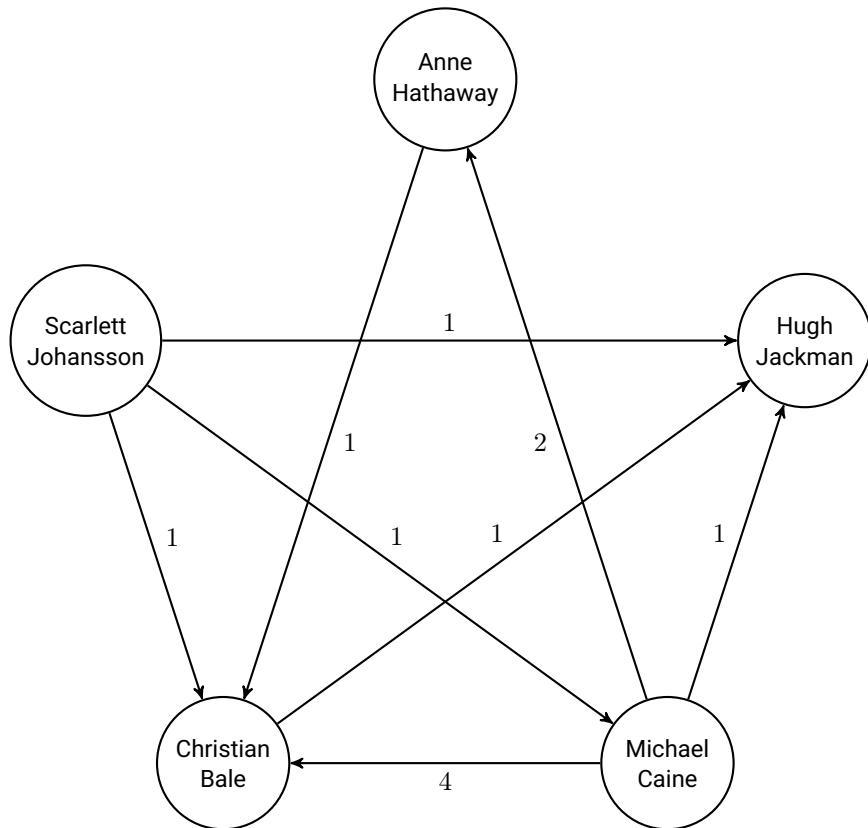

Figure 13.4: A portion of the graph from Problem 6. Michael Caine was in four movies with Christian Bale where Christian Bale was listed first in the cast.

Additional Material

Sparsity

On very large networks, the PageRank algorithm becomes computationally difficult because of the size of the adjacency matrix A . Fortunately, most adjacency matrices are highly sparse, meaning the number of edges is much lower than the number of entries in the matrix. Consider adding functionality to your class from Problem 1 so that it stores \hat{A} as a sparse matrix and performs sparse linear algebra operations in the methods from Problem 2 (use `scipy.sparse.linalg`).

PageRank as a Predictive Model

The data files in Problem 5 include tournament games for their respective seasons, so the resulting rankings naturally align with the outcome of the championship. However, it is also useful to use PageRank as a predictive model: given data for all regular season games, can the outcomes of the tournament games be predicted? Over 40 million Americans fill out 60–100 million March Madness brackets each year and bet over \$9 billion on the tournament, so being able to predict the outcomes of the games is a big deal. See <http://games.espn.com/tournament-challenge-bracket> for more details.

Given regular season data, PageRank can be used to predict tournament results as in Problem 5. There are some pitfalls though; for example, how should ε be chosen? Using $\varepsilon = .5$ with `ncaa2010.csv` minus tournament data (all but the last 63 games in the file) puts UConn—the actual winner that year—in seventh place, while $\varepsilon = .9$ puts UConn in fourth. Both values for ε also rank BYU as number one, but BYU lost in the Sweet Sixteen that year. In practice, Google uses .85 as the damping factor, but there is no rigorous reasoning behind that particular choice.

Other Centrality Measures

In network theory, the *centrality* of a node refers to its importance. Since there are lots of ways to measure importance, there are several different centrality measures.

- *Degree centrality* uses the *degree* of a node, meaning the number of edges adjacent to it (independent of edge direction), for ranking. An academic paper that has been cited many times has a high degree and is considered more important than a paper that has only been cited once.
- *Eigenvector centrality* is an extension of degree centrality. Instead of each neighbor contributing equally to the centrality, nodes that are important are given a higher weight. Thus a node connected to lots of unimportant nodes can have the same measure as a node connected to a few, important nodes. Eigenvector centrality is measured by the eigenvector associated with the largest eigenvalue of the adjacency matrix of the network.
- *Katz centrality* is a modification to eigenvalue centrality for directed networks. Outgoing nodes contribute centrality to their neighbors, so an important node makes its neighbors more important.
- PageRank adapts Katz centrality by averaging out the centrality that a node can pass to its neighbors. For example, if Google—a website that should have high centrality—points to a million websites, then it shouldn’t pass on that high centrality to all of million of its neighbors, so each neighbor gets one millionth of Google’s centrality.

For more information on these centralities, as well as other ways to measure node importance, see [New10].

Iterative Solvers

Lab Objective: Many real-world problems of the form $A\mathbf{x} = \mathbf{b}$ have tens of thousands of parameters. Solving such systems with Gaussian elimination or matrix factorizations could require trillions of floating point operations (FLOPs), which is of course infeasible. Solutions of large systems must therefore be approximated iteratively. In this lab we implement three popular iterative methods for solving large systems: Jacobi, Gauss-Seidel, and Successive Over-Relaxation.

Iterative methods are often useful to solve large systems of equations. In this lab, let $\mathbf{x}^{(k)}$ denote the k th iteration of the iterative method for solving the problem $A\mathbf{x} = \mathbf{b}$ for \mathbf{x} . Furthermore, let x_i be the i th component of \mathbf{x} so that $x_i^{(k)}$ is the i th component of \mathbf{x} in the k th iteration. Like other iterative methods, there are two stopping parameters: a very small $\varepsilon > 0$ and an integer $N \in \mathbb{N}$. Iterations continue until either

$$\|\mathbf{x}^{(k-1)} - \mathbf{x}^{(k)}\| < \varepsilon \quad \text{or} \quad k > N. \quad (14.1)$$

The Jacobi Method

The *Jacobi Method* is a simple but powerful method used for solving certain kinds of large linear systems. The main idea is simple: solve for each variable in terms of the others, then use the previous values to update each approximation. As a (very small) example, consider the 3×3

$$\begin{aligned} 2x_1 &\quad - x_3 = 3, \\ -x_1 + 3x_2 + 2x_3 &= 3, \\ + x_2 + 3x_3 &= -1. \end{aligned}$$

Solving the first equation for x_1 , the second for x_2 , and the third for x_3 yields

$$\begin{aligned} x_1 &= \frac{1}{2}(3 + x_3), \\ x_2 &= \frac{1}{3}(3 + x_1 - 2x_3), \\ x_3 &= \frac{1}{3}(-1 - x_2). \end{aligned}$$

Now begin with an initial guess $\mathbf{x}^{(0)} = [x_1^{(0)}, x_2^{(0)}, x_3^{(0)}]^T = [0, 0, 0]^T$. To compute the first approximation $\mathbf{x}^{(1)}$, use the entries of $\mathbf{x}^{(0)}$ as the variables on the right side of the previous equations:

$$\begin{aligned} x_1^{(1)} &= \frac{1}{2}(3 + x_3^{(0)}) = \frac{1}{2}(3 + 0) = \frac{3}{2}, \\ x_2^{(1)} &= \frac{1}{3}(3 + x_1^{(0)} - 2x_3^{(0)}) = \frac{1}{3}(3 + 0 - 0) = 1, \\ x_3^{(1)} &= \frac{1}{3}(-1 - x_2^{(0)}) = \frac{1}{3}(-1 - 0) = -\frac{1}{3}. \end{aligned}$$

Thus $\mathbf{x}^{(1)} = [\frac{3}{2}, 1, -\frac{1}{3}]^T$. Computing $\mathbf{x}^{(2)}$ is similar:

$$\begin{aligned} x_1^{(2)} &= \frac{1}{2}(3 + x_3^{(1)}) = \frac{1}{2}(3 - \frac{1}{3}) = \frac{4}{3}, \\ x_2^{(2)} &= \frac{1}{3}(3 + x_1^{(1)} - 2x_3^{(1)}) = \frac{1}{3}(3 + \frac{3}{2} + \frac{2}{3}) = \frac{31}{18}, \\ x_3^{(2)} &= \frac{1}{3}(-1 - x_2^{(1)}) = \frac{1}{3}(-1 - 1) = -\frac{2}{3}. \end{aligned}$$

The process is repeated until at least one of the two stopping criteria in (14.1) is met. For this particular problem, convergence to 8 decimal places ($\varepsilon = 10^{-8}$) is reached in 29 iterations.

	$x_1^{(k)}$	$x_2^{(k)}$	$x_3^{(k)}$
$\mathbf{x}^{(0)}$	0	0	0
$\mathbf{x}^{(1)}$	1.5	1	-0.33333333
$\mathbf{x}^{(2)}$	1.33333333	1.72222222	-0.66666667
$\mathbf{x}^{(3)}$	1.16666667	1.88888889	-0.90740741
$\mathbf{x}^{(4)}$	1.04629630	1.99382716	-0.96296296
\vdots	\vdots	\vdots	\vdots
$\mathbf{x}^{(28)}$	0.99999999	2.00000001	-0.99999999
$\mathbf{x}^{(29)}$	1	2	-1

Matrix Representation

The iterative steps performed above can be expressed in matrix form. First, decompose A into its diagonal entries, its entries below the diagonal, and its entries above the diagonal, as $A = D + L + U$.

$$\begin{bmatrix} a_{11} & 0 & \dots & 0 \\ 0 & a_{22} & \dots & 0 \\ \vdots & \vdots & \ddots & \vdots \\ 0 & 0 & \dots & a_{nn} \end{bmatrix} \quad \begin{bmatrix} 0 & 0 & \dots & 0 \\ a_{21} & 0 & \dots & 0 \\ \vdots & \ddots & \ddots & \vdots \\ a_{n1} & \dots & a_{n,n-1} & 0 \end{bmatrix} \quad \begin{bmatrix} 0 & a_{12} & \dots & a_{1n} \\ 0 & 0 & \ddots & \vdots \\ \vdots & \vdots & \ddots & a_{n-1,n} \\ 0 & 0 & \dots & 0 \end{bmatrix}$$

$D \qquad \qquad \qquad L \qquad \qquad \qquad U$

With this decomposition, \mathbf{x} can be expressed in the following way.

$$\begin{aligned} A\mathbf{x} &= \mathbf{b} \\ (D + L + U)\mathbf{x} &= \mathbf{b} \\ D\mathbf{x} &= -(L + U)\mathbf{x} + \mathbf{b} \\ \mathbf{x} &= D^{-1}(-(L + U)\mathbf{x} + \mathbf{b}) \end{aligned}$$

Now using $\mathbf{x}^{(k)}$ as the variables on the right side of the equation to produce $\mathbf{x}^{(k+1)}$ on the left, and noting that $L + U = A - D$, we have the following.

$$\begin{aligned} \mathbf{x}^{(k+1)} &= D^{-1}(-(A - D)\mathbf{x}^{(k)} + \mathbf{b}) \\ &= D^{-1}(D\mathbf{x}^{(k)} - A\mathbf{x}^{(k)} + \mathbf{b}) \\ &= \mathbf{x}^{(k)} + D^{-1}(\mathbf{b} - A\mathbf{x}^{(k)}) \end{aligned} \tag{14.2}$$

There is a potential problem with (14.2): calculating a matrix inverse is the cardinal sin of numerical linear algebra, yet the equation contains D^{-1} . However, since D is a diagonal matrix, D^{-1} is also diagonal, and is easy to compute.

$$D^{-1} = \begin{bmatrix} \frac{1}{a_{11}} & 0 & \dots & 0 \\ 0 & \frac{1}{a_{22}} & \dots & 0 \\ \vdots & \vdots & \ddots & \vdots \\ 0 & 0 & \dots & \frac{1}{a_{nn}} \end{bmatrix}$$

Because of this, the Jacobi method requires that A have nonzero diagonal entries.

The diagonal D can be represented by the 1-dimensional array \mathbf{d} of the diagonal entries. Then the matrix multiplication $D\mathbf{x}$ is equivalent to the component-wise vector multiplication $\mathbf{d} * \mathbf{x} = \mathbf{x} * \mathbf{d}$. Likewise, the matrix multiplication $D^{-1}\mathbf{x}$ is equivalent to the component-wise “vector division” \mathbf{x}/\mathbf{d} .

Problem 1. Write a function that accepts a matrix A , a vector \mathbf{b} , a convergence tolerance tol defaulting to 10^{-8} , and a maximum number of iterations maxiter defaulting to 100. Implement the Jacobi method using (14.2), returning the approximate solution to the equation $A\mathbf{x} = \mathbf{b}$.

Run the iteration until $\|\mathbf{x}^{(k-1)} - \mathbf{x}^{(k)}\|_\infty < \text{tol}$, and only iterate at most maxiter times. Avoid using `la.inv()` to calculate D^{-1} , but use `la.norm()` to calculate the vector ∞ -norm.

Your function should be robust enough to accept systems of any size. To test your function, generate a random \mathbf{b} with `np.random.random()` and use the following function to generate an $n \times n$ matrix A for which the Jacobi method is guaranteed to converge. Run the iteration, then check that $A\mathbf{x}^{(k)}$ and \mathbf{b} are close using `np.allclose()`. There is a file called `test_iterative_solvers.py` that contains prewritten unit tests to test your function for this problem.

```
def diag_dom(n, num_entries=None, as_sparse=False):
    """Generate a strictly diagonally dominant (n, n) matrix.

    Parameters:
        n (int): The dimension of the system.
        num_entries (int): The number of nonzero values.
            Defaults to n^(3/2)-n.
        as_sparse: If True, an equivalent sparse CSR matrix is returned.

    Returns:
        A ((n, n) ndarray): A (n, n) strictly diagonally dominant matrix.
    """
    if num_entries is None:
        num_entries = int(n**1.5) - n
    A = sparse.dok_array((n, n))
    rows = np.random.choice(n, size=num_entries)
    cols = np.random.choice(n, size=num_entries)
    data = np.random.randint(-4, 4, size=num_entries)
    for i in range(num_entries):
        A[rows[i], cols[i]] = data[i]
    B = A.tocsr()           # convert to row format for the next step
    for i in range(n):
        A[i, i] = abs(B[i]).sum() + 1
    return A.tocsr() if as_sparse else A.toarray()
```

Also test your function on random $n \times n$ matrices. If the iteration is non-convergent, the successive approximations will have increasingly large entries.

Convergence

Most iterative methods only converge under certain conditions. For the Jacobi method, convergence mostly depends on the nature of the matrix A . If the entries a_{ij} of A satisfy the property

$$|a_{ii}| > \sum_{j \neq i} |a_{ij}| \quad \text{for all } i = 1, 2, \dots, n,$$

then A is called *strictly diagonally dominant* (`diag_dom()` in Problem 1 generates a strictly diagonally dominant $n \times n$ matrix). If this is the case,¹ then the Jacobi method always converges, regardless of the initial guess \mathbf{x}_0 . This is a very different convergence result than many other iterative methods such as Newton's method where convergence is highly sensitive to the initial guess.

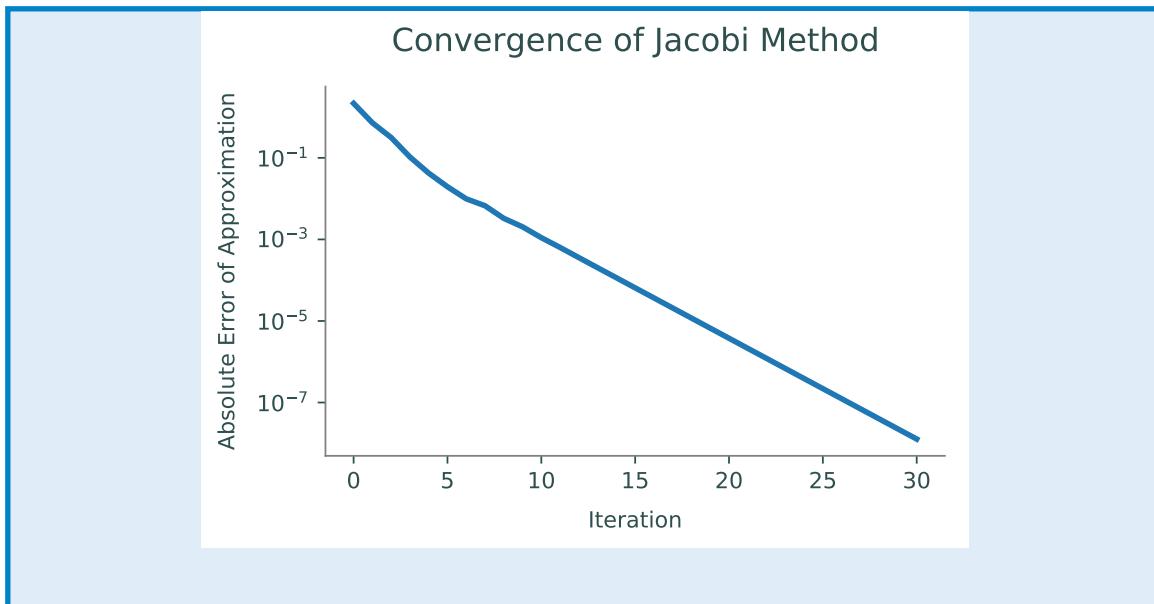

There are a few ways to determine whether or not an iterative method is converging. For example, since the approximation $\mathbf{x}^{(k)}$ should satisfy $A\mathbf{x}^{(k)} \approx \mathbf{b}$, the normed difference $\|A\mathbf{x}^{(k)} - \mathbf{b}\|_\infty$ should be small. This value is called the *absolute error* of the approximation. If the iterative method converges, the absolute error should decrease to ε .

Problem 2. Modify your Jacobi method function in the following ways.

1. Add a keyword argument called `plot`, defaulting to `False`.
2. Keep track of the absolute error $\|A\mathbf{x}^{(k)} - \mathbf{b}\|_\infty$ of the approximation at each iteration.
3. If `plot` is `True`, produce a lin-log plot (use `plt.semilogy()`) of the error against iteration count. Remember to still return the approximate solution \mathbf{x} .

If the iteration converges, your plot should resemble the following figure.

¹Although this seems like a strong requirement, most real-world linear systems can be represented by strictly diagonally dominant matrices.

The Gauss-Seidel Method

The *Gauss-Seidel method* is essentially a slight modification of the Jacobi method. The main difference is that in Gauss-Seidel, new information is used immediately. As an example, consider again the system from the previous section,

$$\begin{aligned} 2x_1 - x_3 &= 3, \\ -x_1 + 3x_2 + 2x_3 &= 3, \\ +x_2 + 3x_3 &= -1. \end{aligned}$$

As with the Jacobi method, solve for x_1 in the first equation, x_2 in the second equation, and x_3 in the third equation:

$$\begin{aligned} x_1 &= \frac{1}{2}(3 + x_3), \\ x_2 &= \frac{1}{3}(3 + x_1 - 2x_3), \\ x_3 &= \frac{1}{3}(-1 - x_2). \end{aligned}$$

Using $\mathbf{x}^{(0)}$ to compute $x_1^{(1)}$ in the first equation as before,

$$x_1^{(1)} = \frac{1}{2}(3 + x_3^{(0)}) = \frac{1}{2}(3 + 0) = \frac{3}{2}.$$

Now, however, use the updated value of $x_1^{(1)}$ in the calculation of $x_2^{(1)}$:

$$x_2^{(1)} = \frac{1}{3}(3 + x_1^{(1)} - 2x_3^{(0)}) = \frac{1}{3}\left(3 + \frac{3}{2} - 0\right) = \frac{3}{2}.$$

Likewise, use the updated values of $x_1^{(1)}$ and $x_2^{(1)}$ to calculate $x_3^{(1)}$:

$$x_3^{(1)} = \frac{1}{3}(-1 - x_2^{(1)}) = \frac{1}{3}\left(-1 - \frac{3}{2}\right) = -\frac{5}{6}.$$

This process of using calculated information immediately is called *forward substitution*, and causes the algorithm to (generally) converge much faster.

	$x_1^{(k)}$	$x_2^{(k)}$	$x_3^{(k)}$
$x^{(0)}$	0	0	0
$x^{(1)}$	1.5	1.5	-0.83333333
$x^{(2)}$	1.08333333	1.91666667	-0.97222222
$x^{(3)}$	1.01388889	1.98611111	-0.99537037
$x^{(4)}$	1.00231481	1.99768519	-0.99922840
\vdots	\vdots	\vdots	\vdots
$x^{(11)}$	1.00000001	1.99999999	-1
$x^{(12)}$	1	2	-1

Notice that Gauss-Seidel converges in less than half as many iterations as Jacobi does for this system.

Implementation

Because Gauss-Seidel updates only one element of the solution vector at a time, **the iteration cannot be summarized by a single matrix equation**. Instead, the process is most generally described by the equation

$$x_i^{(k+1)} = \frac{1}{a_{ii}} \left(b_i - \sum_{j < i} a_{ij} x_j^{(k+1)} - \sum_{j > i} a_{ij} x_j^{(k)} \right). \quad (14.3)$$

Let \mathbf{a}_i be the i th row of A and let $\hat{\mathbf{x}}_i^{(k)} = (x_1^{(k+1)}, \dots, x_{i-1}^{(k+1)}, x_i^{(k)}, x_{i+1}^{(k)}, \dots, x_n^{(k)})$. The two sums are the regular vector product of \mathbf{a}_i and $\hat{\mathbf{x}}_i^{(k)}$ without the i^{th} term $a_{ii}x_i^{(k)}$. This suggests the simplification

$$\begin{aligned} x_i^{(k+1)} &= \frac{1}{a_{ii}} \left(b_i - \mathbf{a}_i^\top \hat{\mathbf{x}}_i^{(k)} + a_{ii}x_i^{(k)} \right) \\ &= x_i^{(k)} + \frac{1}{a_{ii}} \left(b_i - \mathbf{a}_i^\top \hat{\mathbf{x}}_i^{(k)} \right). \end{aligned} \quad (14.4)$$

One sweep through all the entries of \mathbf{x} completes one iteration.

Problem 3. Write a function that accepts a matrix A , a vector \mathbf{b} , a convergence tolerance `tol` defaulting to 10^{-8} , a maximum number of iterations `maxiter` defaulting to 100, and a keyword argument `plot` that defaults to `False`. Implement the Gauss-Seidel method using (14.4) and details from the example above. Return the approximate solution to the equation $A\mathbf{x} = \mathbf{b}$.

Use the same stopping criterion as in Problem 1. Also keep track of the absolute errors of the iteration, as in Problem 2. If `plot` is `True`, plot the error against iteration count. Use `diag_dom()` to generate test cases.

ACHTUNG!

Since the Gauss-Seidel algorithm operates on the approximation vector in place (modifying it one entry at a time), the previous approximation $\mathbf{x}^{(k-1)}$ must be stored at the beginning of the k th iteration in order to calculate $\|\mathbf{x}^{(k-1)} - \mathbf{x}^{(k)}\|_\infty$. Additionally, since NumPy arrays are mutable, the past iteration must be stored as a **copy**.

```
>>> x0 = np.random.random(5)          # Generate a random vector.
>>> x1 = x0                        # Attempt to make a copy.
>>> x1[3] = 1000                   # Modify the "copy" in place.
>>> np.allclose(x0, x1)            # But x0 was also changed!
True

# Instead, make a copy of x0 when creating x1.
>>> x0 = np.copy(x1)              # Make a copy.
>>> x1[3] = -1000
>>> np.allclose(x0, x1)
False
```

Convergence

Whether or not the Gauss-Seidel method converges depends on the nature of A . If all of the eigenvalues of A are positive, A is called *positive definite*. If A is positive definite *or* if it is strictly diagonally dominant, then the Gauss-Seidel method converges regardless of the initial guess $\mathbf{x}^{(0)}$.

Solving Sparse Systems Iteratively

Iterative solvers are best suited for solving very large sparse systems. However, using the Gauss-Seidel method on sparse matrices requires translating code from NumPy to `scipy.sparse`. The algorithm is the same, but there are some functions that are named differently between these two packages.²

Problem 4. Write a new function that accepts a **sparse** matrix A , a vector **b**, a convergence tolerance `tol`, and a maximum number of iterations `maxiter` (plotting the convergence is not required for this problem). Implement the Gauss-Seidel method using (14.4), returning the approximate solution to the equation $A\mathbf{x} = \mathbf{b}$. Use the usual default stopping criterion.

The Gauss-Seidel method requires extracting the rows A_i from the matrix A and computing $A_i^T\mathbf{x}$. There are many ways to do this that cause some fairly serious runtime issues, so we provide the code for this specific portion of the algorithm.

```
# Get the indices of where the i-th row of A starts and ends if the
# nonzero entries of A were flattened.
rowstart = A.indptr[i]
```

²See the lab on Linear Systems for a review of `scipy.sparse` matrices and syntax.

```

rowend = A.indptr[i+1]

# Multiply only the nonzero elements of the i-th row of A with the
# corresponding elements of x.
Aix = A.data[rowstart:rowend] @ x[A.indices[rowstart:rowend]]

```

To test your function, remember to call `diag_dom()` using `as_sparse=True`

```

>>> A = diag_dom(1000, as_sparse=True)
>>> b = np.random.random(1000)

```

UNIT TEST

There is a file called `test_iterative_solvers.py` that contains prewritten unit tests for Problem 1. There is a place for you to add your own unit tests to test your function for Problem 4, which will be graded.

Successive Over-Relaxation

There are many systems that meet the requirements for convergence with the Gauss-Seidel method, but for which convergence is still relatively slow. A slightly altered version of the Gauss-Seidel method, called *Successive Over-Relaxation* (SOR), can result in faster convergence. This is achieved by introducing a *relaxation factor* $\omega \geq 1$ and modifying (14.3) as

$$x_i^{(k+1)} = (1 - \omega)x_i^{(k)} + \frac{\omega}{a_{ii}} \left(b_i - \sum_{j < i} a_{ij}x_j^{(k)} - \sum_{j > i} a_{ij}x_j^{(k)} \right).$$

Simplifying the equation, we have

$$x_i^{(k+1)} = x_i^{(k)} + \frac{\omega}{a_{ii}} \left(b_i - \mathbf{a}_i^T \mathbf{x}^{(k)} \right). \quad (14.5)$$

Note that when $\omega = 1$, SOR reduces to Gauss-Seidel. The relaxation factor ω weights the new iteration between the current best approximation and the next approximation in a way that can sometimes dramatically improve convergence.

Problem 5. Write a function that accepts a sparse matrix A , a vector \mathbf{b} , a relaxation factor ω , a convergence tolerance `tol`, and a maximum number of iterations `maxiter`. Implement SOR using (14.5), compute the approximate solution to the equation $A\mathbf{x} = \mathbf{b}$. Use the usual stopping criterion. Return the approximate solution \mathbf{x} as well as a boolean indicating whether the function converged and the number of iterations computed.

(Hint: this requires changing only one line of code from the sparse Gauss-Seidel function.)

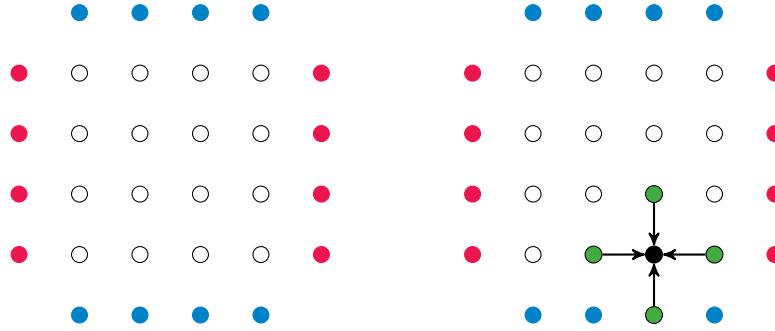

Figure 14.1: On the left, an example of a 6×6 grid ($n = 4$) where the red dots are hot boundary zones and the blue dots are cold boundary zones. On the right, the green dots are the neighbors of the interior black dot that are used to approximate the heat at the black dot.

A Finite Difference Method

Laplace's equation is an important partial differential equation that arises often in both pure and applied mathematics. In two dimensions, the equation has the following form.

$$\frac{\partial^2 u}{\partial x^2} + \frac{\partial^2 u}{\partial y^2} = 0 \quad (14.6)$$

Laplace's equation can be used to model heat flow. Consider a square metal plate where the top and bottom borders are fixed at 0° Celsius and the left and right sides are fixed at 100° Celsius. Given these boundary conditions, we want to describe how heat diffuses through the rest of the plate. The solution to Laplace's equation describes the plate when it is in a *steady state*, meaning that the heat at a given part of the plate no longer changes with time.

It is possible to solve (14.6) analytically. However, the problem can also be solved numerically using a *finite difference method*. To begin, we impose a discrete, square grid on the plate with uniform spacing. Denote the points on the grid by (x_i, y_j) and the value of u at these points (the heat) as $u(x_i, y_j) = U_{i,j}$. Using the centered difference quotient for second derivatives to approximate the partial derivatives,

$$\begin{aligned} 0 &= \frac{\partial^2 u}{\partial x^2} + \frac{\partial^2 u}{\partial y^2} \\ &\approx \frac{U_{i+1,j} - 2U_{i,j} + U_{i-1,j}}{h^2} + \frac{U_{i,j+1} - 2U_{i,j} + U_{i,j-1}}{h^2} \\ &= \frac{1}{h^2} (-4U_{i,j} + U_{i+1,j} + U_{i-1,j} + U_{i,j+1} + U_{i,j-1}), \end{aligned} \quad (14.7)$$

where $h = x_{i+1} - x_i = y_{j+1} - y_j$ is the distance between the grid points in either direction. This problem can be formulated as a linear system. Suppose the grid has exactly $(n+2) \times (n+2)$ entries. Then the interior of the grid (where $u(x, y)$ is unknown) is $n \times n$, and can be flattened into an $n^2 \times 1$ vector \mathbf{u} . The entire first row goes first, then the second row, proceeding to the n th row.

$$\mathbf{u} = [U_{1,1} \quad U_{1,2} \quad \cdots \quad U_{1,n} \quad U_{2,1} \quad U_{2,2} \quad \cdots \quad U_{2,n} \quad \cdots \quad U_{n,n}]^\top$$

From (14.7), for an interior point $U_{i,j}$, we have

$$-4U_{i,j} + U_{i+1,j} + U_{i-1,j} + U_{i,j+1} + U_{i,j-1} = 0. \quad (14.8)$$

If any of the neighbors to $U_{i,j}$ is a boundary point on the grid, its value is already determined by the boundary conditions. For example, the neighbor $U_{3,0}$ of the gridpoint for $U_{3,1}$ is fixed at $U_{3,0} = 100$. In this case, (14.8) becomes

$$-4U_{3,1} + U_{2,1} + U_{3,2} + U_{4,1} = -100.$$

The constants on the right side of (14.8) become the $n^2 \times 1$ vector \mathbf{b} . All nonzero entries of \mathbf{b} correspond to interior points that touch the left or right boundaries.

As an example, writing (14.8) for the 16 interior points of the grid in Figure 14.1 results in the following 16×16 system $A\mathbf{u} = \mathbf{b}$. Note the block structure (empty blocks are all zeros).

$$\left[\begin{array}{cccc|cccc|c|c|c|c|c|c|c|c} -4 & 1 & 0 & 0 & 1 & 0 & 0 & 0 & & & & & & & & \\ 1 & -4 & 1 & 0 & 0 & 1 & 0 & 0 & & & & & & & & \\ 0 & 1 & -4 & 1 & 0 & 0 & 1 & 0 & & & & & & & & \\ 0 & 0 & 1 & -4 & 0 & 0 & 0 & 1 & & & & & & & & \\ \hline 1 & 0 & 0 & 0 & -4 & 1 & 0 & 0 & 1 & 0 & 0 & 0 & & & & \\ 0 & 1 & 0 & 0 & 1 & -4 & 1 & 0 & 0 & 1 & 0 & 0 & & & & \\ 0 & 0 & 1 & 0 & 0 & 1 & -4 & 1 & 0 & 0 & 1 & 0 & & & & \\ 0 & 0 & 0 & 1 & 0 & 0 & 1 & -4 & 0 & 0 & 0 & 1 & & & & \\ \hline & & & & 1 & 0 & 0 & 0 & -4 & 1 & 0 & 0 & 1 & 0 & 0 & 0 \\ & & & & 0 & 1 & 0 & 0 & 1 & -4 & 1 & 0 & 0 & 1 & 0 & 0 \\ & & & & 0 & 0 & 1 & 0 & 0 & 1 & -4 & 1 & 0 & 0 & 1 & 0 \\ & & & & 0 & 0 & 0 & 1 & 0 & 0 & 1 & -4 & 0 & 0 & 0 & 1 \\ \hline & & & & 1 & 0 & 0 & 0 & 0 & -4 & 1 & 0 & 0 & 0 & & \\ & & & & 0 & 1 & 0 & 0 & 0 & 1 & -4 & 1 & 0 & & \\ & & & & 0 & 0 & 1 & 0 & 0 & 0 & 1 & -4 & 1 & & \\ & & & & 0 & 0 & 0 & 1 & 0 & 0 & 0 & 1 & -4 & & \\ \hline & & & & 1 & 0 & 0 & 0 & 0 & 0 & -4 & 1 & 0 & 0 & & \\ & & & & 0 & 1 & 0 & 0 & 0 & 1 & -4 & 1 & 0 & & \\ & & & & 0 & 0 & 1 & 0 & 0 & 0 & 1 & -4 & 1 & & \\ & & & & 0 & 0 & 0 & 1 & 0 & 0 & 0 & 1 & -4 & & \\ \hline \end{array} \right] = \left[\begin{array}{c} U_{1,1} \\ U_{1,2} \\ U_{1,3} \\ U_{1,4} \\ \hline U_{2,1} \\ U_{2,2} \\ U_{2,3} \\ U_{2,4} \\ \hline U_{3,1} \\ U_{3,2} \\ U_{3,3} \\ U_{3,4} \\ \hline U_{4,1} \\ U_{4,2} \\ U_{4,3} \\ U_{4,4} \end{array} \right] = \left[\begin{array}{c} -100 \\ 0 \\ 0 \\ -100 \\ \hline -100 \\ 0 \\ 0 \\ -100 \\ \hline -100 \\ 0 \\ 0 \\ -100 \\ \hline -100 \\ 0 \\ 0 \\ -100 \end{array} \right]$$

More concisely, for any positive integer n , the matrix A can be written as

$$A = \left[\begin{array}{ccccc} B & I & & & \\ I & B & I & & \\ & I & \ddots & \ddots & \\ & & \ddots & \ddots & I \\ & & & I & B \end{array} \right], \quad \text{where } B = \left[\begin{array}{ccccc} -4 & 1 & & & \\ 1 & -4 & 1 & & \\ & 1 & \ddots & \ddots & \\ & & \ddots & \ddots & 1 \\ & & & 1 & -4 \end{array} \right] \text{ is } n \times n.$$

Problem 6. Write a function that accepts an integer n , a relaxation factor ω , a convergence tolerance `tol` that defaults to 10^{-8} , a maximum number of iterations `maxiter` that defaults to 100, and a bool `plot` that defaults to `False`. Generate and solve the corresponding system $A\mathbf{u} = \mathbf{b}$ using Problem 5. Also return a boolean indicating whether the function converged and the number of iterations computed.

(Hint: see Problem 5 of the Linear Systems lab for the construction of A . Also, `np.tile()` may be useful for constructing \mathbf{b} .)

If `plot=True`, visualize the solution \mathbf{u} with a heatmap using `plt.pcolormesh()` (the colormap "coolwarm" is a good choice in this case). This shows the distribution of heat over the hot plate after it has reached its steady state. Note that the \mathbf{u} must be reshaped as an $n \times n$ array to properly visualize the result.

ACHTUNG!

Integer arrays are generally not suitable for iterative methods that need to converge. Float arrays should be used instead. To ensure that the array being passed into your iterative method is of the desired datatype use `b.astype(float)` where `b` is the array in question.

Problem 7. To demonstrate how convergence is affected by the value of the relaxation factor ω in SOR, run your function from Problem 6 with $\omega = 1, 1.05, 1.1, \dots, 1.9, 1.95$ and $n = 20$. Plot the number of computed iterations as a function of ω . Return the value of ω that results in the least number of iterations.

Note that the matrix A from Problem 6 is not strictly diagonally dominant. However, A is positive definite, so the algorithm will converge. Unfortunately, convergence for these kinds of systems usually requires more iterations than for strictly diagonally dominant systems. Therefore, set `tol=1e-2` and `maxiter=1000`.

Recall that $\omega = 1$ corresponds to the Gauss-Seidel method. Choosing a more optimal relaxation factor saves a large number of iterations. This could translate to saving days or weeks of computation time while solving extremely large linear systems on a supercomputer.

The Drazin Inverse

Lab Objective: *The Drazin inverse of a matrix is a pseudoinverse which preserves certain spectral properties of the matrix. In this lab we compute the Drazin inverse using the Schur decomposition, then use it to compute the effective resistance of a graph and perform link prediction.*

Definition of the Drazin Inverse

The *index* of an $n \times n$ matrix A is the smallest nonnegative integer k for which $\mathcal{N}(A^k) = \mathcal{N}(A^{k+1})$. The *Drazin inverse* A^D of A is the unique $n \times n$ matrix satisfying the following properties.

- $AA^D = A^DA$
- $A^{k+1}A^D = A^k$
- $A^DAA^D = A^D$

Note that if A is *invertible*, in which case $k = 0$, then $A^D = A^{-1}$. On the other hand, if A is *nilpotent*, meaning $A^j = \mathbf{0}$ for some nonnegative integer j , then A^D is the zero matrix.

Problem 1. Write a function that accepts an $n \times n$ matrix A , the index k of A , and an $n \times n$ matrix A^D . Use the criteria described above to determine whether or not A^D is the Drazin inverse of A . Return `True` if A^D satisfies all three conditions; otherwise, return `False`.

Use the following matrices as test cases for your function.

$$A = \begin{bmatrix} 1 & 3 & 0 & 0 \\ 0 & 1 & 3 & 0 \\ 0 & 0 & 1 & 3 \\ 0 & 0 & 0 & 0 \end{bmatrix}, \quad A^D = \begin{bmatrix} 1 & -3 & 9 & 81 \\ 0 & 1 & -3 & -18 \\ 0 & 0 & 1 & 3 \\ 0 & 0 & 0 & 0 \end{bmatrix}, \quad k = 1$$

$$B = \begin{bmatrix} 1 & 1 & 3 \\ 5 & 2 & 6 \\ -2 & -1 & -3 \end{bmatrix}, \quad B^D = \begin{bmatrix} 0 & 0 & 0 \\ 0 & 0 & 0 \\ 0 & 0 & 0 \end{bmatrix}, \quad k = 3$$

(Hint: `np.allclose()` and `np.linalg.matrix_power()` may be useful).

Computing the Drazin Inverse

The Drazin inverse is often defined theoretically in terms of the eigenprojections of a matrix. However, eigenprojections are often costly or unstable to calculate, so we resort to a different method to calculate the Drazin inverse.

Every $n \times n$ matrix A can be written in the form

$$A = S^{-1} \begin{bmatrix} M & \mathbf{0} \\ \mathbf{0} & N \end{bmatrix} S, \quad (15.1)$$

where S is a change of basis matrix, M is nonsingular, and N is nilpotent. Then the Drazin inverse can be calculated as

$$A^D = S^{-1} \begin{bmatrix} M^{-1} & \mathbf{0} \\ \mathbf{0} & \mathbf{0} \end{bmatrix} S. \quad (15.2)$$

To put A into the form in (15.1), we can use the *Schur decomposition* of A , given by

$$A = QTQ^{-1}, \quad (15.3)$$

where Q is orthonormal and T is upper triangular. Since T is similar to A , the eigenvalues of A are listed along the diagonal of T . If A is singular, at least one diagonal entry of T must be 0.

In general, Schur decompositions are not unique; the eigenvalues along the diagonal of T can be reordered. To find M , N , and S , we compute the Schur decomposition of A twice, ordering the eigenvalues differently in each decomposition.

First, we sort so that the nonzero eigenvalues are listed first along the diagonal of T . Then, if k is the number of nonzero eigenvalues, the upper left $k \times k$ block of T forms the nonsingular matrix M , and the first k columns of Q form the first k columns of the change of basis matrix S .

Computing the decomposition a second time, we reorder so that the 0 eigenvalues are listed first along the diagonal of T . Then the upper left $(n - k) \times (n - k)$ block forms the nilpotent matrix N , and the first $n - k$ columns of Q form the last $n - k$ columns of S . This completes a change of basis matrix that will put A into the desired block diagonal form. Lastly, we use (15.2) to compute A^D .

SciPy's `la.schur()` is a routine for computing the Schur decomposition of a matrix, but it does not automatically sort it by eigenvalue. However, sorting can be accomplished by specifying the `sort` keyword argument. Given an eigenvalue, the sorting function should return a boolean indicating whether to sort that eigenvalue to the top left of the diagonal of T .

```
>>> from scipy import linalg as la

# The standard Schur decomposition.
>>> A = np.array([[0, 0, 2], [-3, 2, 6], [0, 0, 1]])
>>> T, Z = la.schur(A)
>>> T
# The eigenvalues (2, 0, and 1) are not sorted.
array([[ 2., -3.,  6.],
       [ 0.,  0.,  2.],
       [ 0.,  0.,  1.]])\n\n# Specify a sorting function to get the desired result.
>>> f = lambda x: abs(x) > 0
>>> T1, Z1, k = la.schur(A, sort=f)
>>> T1
```

```

array([[ 2.        ,  0.        ,  6.70820393],
       [ 0.        ,  1.        ,  2.        ],
       [ 0.        ,  0.        ,  0.        ]])
>>> k                         # k is the number of columns satisfying the sort,
2                               # which is the number of nonzero eigenvalues.

```

The procedure for finding the Drazin inverse using the Schur decomposition is given in Algorithm 1. Due to possible floating point arithmetic errors, consider all eigenvalues smaller than a certain tolerance to be 0.

Algorithm 1

```

1: procedure DRAZIN( $A$ , tol)
2:    $(n, n) \leftarrow \text{shape}(A)$ 
3:    $T_1, Q_1, k_1 \leftarrow \text{schur}(A, |x| > \text{tol})$        $\triangleright$  Sort the Schur decomposition with 0 eigenvalues last.
4:    $T_2, Q_2, k_2 \leftarrow \text{schur}(A, |x| \leq \text{tol})$        $\triangleright$  Sort the Schur decomposition with 0 eigenvalues first.
5:    $U \leftarrow [Q_{1,:k_1} \mid Q_{2,:n-k_1}]$                    $\triangleright$  Create change of basis matrix.
6:    $U^{-1} \leftarrow \text{inverse}(U)$ 
7:    $V \leftarrow U^{-1}AU$                                       $\triangleright$  Find block diagonal matrix in (15.1)
8:    $Z \leftarrow \mathbf{0}_{n \times n}$ 
9:   if  $k_1 \neq 0$  then
10:     $M^{-1} \leftarrow \text{inverse}(V_{:k_1,:k_1})$ 
11:     $Z_{:k_1,:k_1} \leftarrow M^{-1}$ 
12:   return  $UZU^{-1}$ 

```

Problem 2. Write a function that accepts an $n \times n$ matrix A and a tolerance for rounding eigenvalues to zero. Use Algorithm 1 to compute the Drazin inverse A^D . Use your function from Problem 1 to verify your implementation.

ACHTUNG!

Because the algorithm for the Drazin inverse requires calculation of the inverse of a matrix, it is unstable when that matrix has a high condition number. If the algorithm does not find the correct Drazin inverse, check the condition number of V from Algorithm 1

NOTE

The Drazin inverse is called a *pseudoinverse* because $A^D = A^{-1}$ for invertible A , and for noninvertible A , A^D always exists and acts similarly to an inverse. There are other matrix pseudoinverses that preserve different qualities of A , including the *Moore-Penrose pseudoinverse* A^\dagger , which can be thought of as the least squares approximation to A^{-1} .

Applications of the Drazin Inverse

Effective Resistance

The *effective resistance* between two nodes in a undirected graph is a measure of how connected those nodes are. The concept originates from the study of circuits to measure the resistance between two points on the circuit. A *resistor* is a device in a circuit which limits or regulates the flow of electricity. Two points that have more resistors between them have more resistance, while those with fewer resistors between them have less resistance. The entire circuit can be represented by a graph where the nodes are the points of interest and the number of edges connecting two nodes indicates the number of resistors between the corresponding points. See Figure 15.1 for an example.

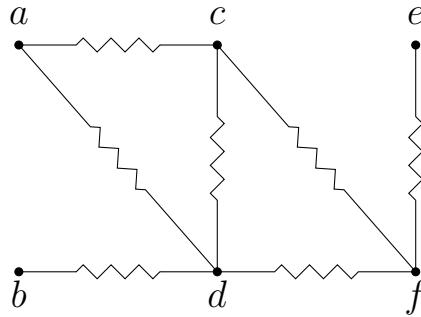

Figure 15.1: A graph with a resistor on each edge.

In electromagnetism, there are rules for manually calculating the effective resistance between two nodes for relatively simple graphs. However, this is infeasible for large or complicated graphs. Instead, we can use the Drazin inverse to calculate effective resistance for any graph.

First, create the *adjacency matrix*¹ of the graph, the matrix where the (ij) th entry is the number of connections from node i to node j . Next, calculate the Laplacian L of the adjacency matrix. Then if R_{ij} is the effective resistance from node i to node j ,

$$R_{ij} = \begin{cases} (\tilde{L}^j)_ii^D & \text{if } i \neq j \\ 0 & \text{if } i = j, \end{cases} \quad (15.4)$$

where \tilde{L}^j is the Laplacian with the j th row of the Laplacian replaced by the j th row of the identity matrix, and $(\tilde{L}^j)^D$ is its Drazin inverse.

Problem 3. Write a function that accepts the $n \times n$ adjacency matrix of an undirected graph. Use (15.4) to compute the effective resistance from each node to every other node. Return an $n \times n$ matrix where the (ij) th entry is the effective resistance from node i to node j . Keep the following in mind:

- The resulting matrix should be symmetric.
- The effective resistance from a node to itself is 0.

¹See Problem 1 of Image Segmentation for a refresher on adjacency matrices and the Laplacian.

- Consider creating the matrix column by column instead of entry by entry. Every time you compute the Drazin inverse, the whole diagonal of the matrix can be used.

Test your function using the graphs and values from Figure 15.2.

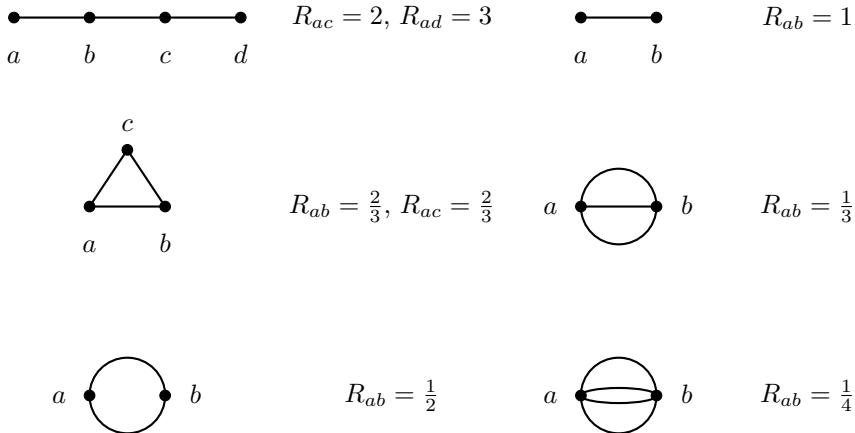

Figure 15.2: The effective resistance between two points for several simple graphs. Nodes that are farther apart have a larger effective resistance, while nodes that are nearer or better connected have a smaller effective resistance.

Link Prediction

Link prediction is the problem of predicting the likelihood of a future association between two unconnected nodes in a graph. Link prediction has application in many fields, but the canonical example is friend suggestions on Facebook. The Facebook network can be represented by a large graph where each user is a node, and two nodes have an edge connecting them if they are “friends.” Facebook aims to predict who you would like to become friends with in the future, based on who you are friends with now, as well as discover which friends you may have in real life that you have not yet connected with online. To do this, Facebook must have some way to measure how closely two users are connected.

We will compute link prediction using effective resistance as a metric. Effective resistance measures how closely two nodes are connected, and nodes that are closely connected at present are more likely to be connected in the future. Given an undirected graph, the next link should connect the two unconnected nodes with the least effective resistance between them.

Problem 4. Write a class called `LinkPredictor` for performing link prediction. Implement the `__init__()` method so that it accepts the name of a `csv` file containing information about a social network. Each row of the file should contain the names of two nodes which are connected by an (undirected) edge.

Store each of the names of the nodes of the graph as an ordered list. Next, create the adjacency matrix for the network where the i th row and column of the matrix correspond to the i th member of the list of node names. Finally, use your function from Problem 3 to compute the effective resistance matrix. Save the list of names, the adjacency matrix, and the effective resistance matrix as attributes.

Problem 5. Implement the following methods in the `LinkPredictor` class:

1. `predict_link()`: Accept a parameter `node` which is either `None` or a string representing a node in the network. If `node` is `None`, return a tuple with the names of the nodes between which the next link should occur. However, if `node` is a string, return the name of the node which should be connected to `node` next out of all other nodes in the network. If `node` is not in the network, raise a `ValueError`. Take the following into consideration:
 - (a) You want to find the two nodes which have the smallest effective resistance between them which are not yet connected. Use information from the adjacency matrix to zero out all entries of the effective resistance matrix that represent connected nodes. The "*" operator multiplies arrays component-wise, which may be helpful.
 - (b) Find the next link by finding the minimum value of the array that is nonzero. Your array may be the whole matrix or just a column if you are only considering links for a certain node. This can be accomplished by passing `np.min()` a masked version of your matrix to exclude entries that are 0.
 - (c) NumPy's `np.where()` is useful for finding the minimum value in an array:

```
>>> A = np.random.randint(-9, 9, (3, 3))
>>> A
array([[ 6, -8, -9],
       [-2,  1, -1],
       [ 4,  0, -3]])

# Find the minimum value in the array.
>>> minval = np.min(A)
>>> minval
-9

# Find the location of the minimum value.
>>> loc = np.where(A==minval)
>>> loc
(array([0], dtype=int64), array([2], dtype=int64))
```

2. `add_link()`: Take as input two names of nodes, and add a link between them. If either name is not in the network, raise a `ValueError`. Add the link by updating the adjacency matrix and the effective resistance matrix.

Figure 15.3 visualizes the data in `social_network.csv`. Use this graph to verify that your class is suggesting plausible new links. You should observe the following:

- In the entire network, Emily and Oliver are most likely to become friends next.
- Melanie is predicted to become friends with Carol next.
- Alan is expected to become friends with Sonia, then with Piers, and then with Abigail.

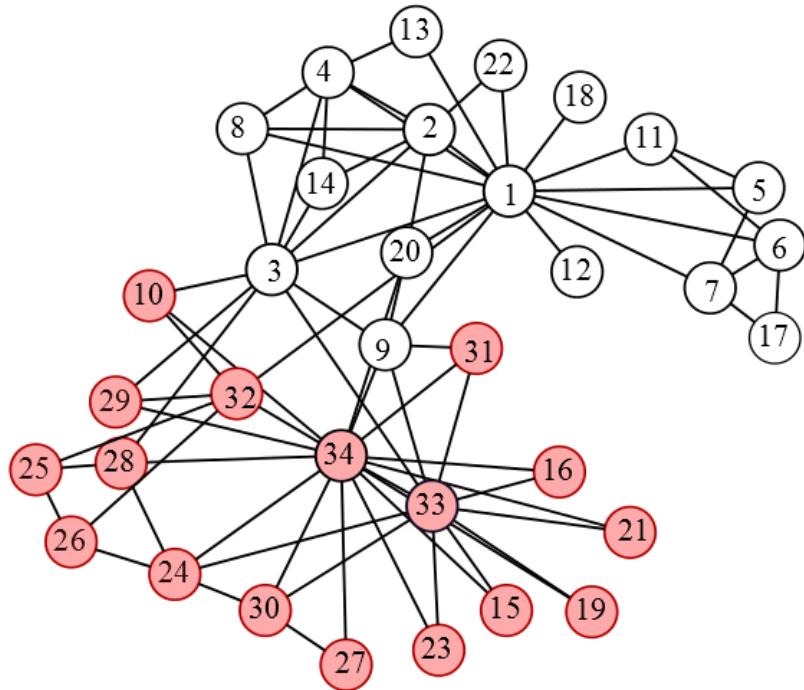

Figure 15.3: The social network contained in `social_network.csv`. Adapted from data by Wayne W Zachary (see https://en.wikipedia.org/wiki/Zachary%27s_karate_club).

1. Piers	10. Alan	19. Max	28. Thomas

9. Penelope	18. John	27. Brandon	34. Emily

16

The Arnoldi Iteration

Lab Objective: *The Arnoldi Iteration is an efficient method for finding the eigenvalues of extremely large matrices. Instead of using standard methods, the iteration uses Krylov subspaces to approximate how a linear operator acts on vectors. With this approach, the Arnoldi Iteration facilitates the computation of eigenvalues for enormous matrices without needing to physically create the matrix in memory. We will explore this subject by implementing the Arnoldi iteration algorithm, using our implementation for eigenvalue computation, and then graphically representing the accuracy of our approximated eigenvalues.*

Krylov Subspaces

One of the biggest difficulties in numerical linear algebra is the amount of memory needed to store a large matrix and the amount of time needed to read its entries. Methods using Krylov subspaces avoid this difficulty by studying how a matrix acts on vectors, making it unnecessary in many cases to create the matrix itself.

The *Arnoldi Iteration* is an algorithm for finding an orthonormal basis of a Krylov subspace. One of its strengths is that it can run on any linear operator without knowing the operator's underlying matrix representation. The outputs of the Arnoldi algorithm can then be used to approximate the eigenvalues of the matrix of the linear operator.

The order- n Krylov subspace of A generated by \mathbf{x} is

$$\mathcal{K}_n(A, \mathbf{x}) = \text{span}\{\mathbf{x}, A\mathbf{x}, A^2\mathbf{x}, \dots, A^{n-1}\mathbf{x}\}.$$

If the vectors $\{\mathbf{x}, A\mathbf{x}, A^2\mathbf{x}, \dots, A^{n-1}\mathbf{x}\}$ are linearly independent, then they form a basis for $\mathcal{K}_n(A, \mathbf{x})$. However, $A^n\mathbf{x}$ frequently converges to a dominant eigenvector of A as n gets large, which fills the basis with many almost parallel vectors. This yields a basis prone to ill-conditioned computations and numerical instability.

The Arnoldi Iteration Algorithm

The Arnoldi iteration focuses on efficiently creating an orthonormal basis for $\mathcal{K}_n(A, \mathbf{x})$ by integrating the creation of $\{\mathbf{x}, A\mathbf{x}, A^2\mathbf{x}, \dots, A^{n-1}\mathbf{x}\}$ with the modified Gram-Schmidt algorithm. This process yields an orthonormal basis for $\mathcal{K}_n(A, \mathbf{x})$ that can be used for further computations.

The algorithm begins by initializing a matrix H which will be an upper Hessenberg matrix and a matrix Q which will be filled with the basis vectors of our Krylov subspace. It also requires an initial vector $\mathbf{b} \neq 0$ which is normalized to get $\mathbf{q}_1 = \mathbf{b} / \|\mathbf{b}\|$. This represents the basis for the initial Krylov subspace, $\mathcal{K}_1(A, \mathbf{b})$.

For the k th iteration, compute the next basis vector \mathbf{q}_{k+1} by using the modified Gram-Schmidt process to make $A\mathbf{q}_k$ orthonormal to \mathbf{q}_k . This entails making each column of Q orthogonal to \mathbf{q}_k before proceeding to the next iteration. The vectors $\{\mathbf{q}_i\}_{i=1}^k$ are then a basis for $\mathcal{K}_k(A, \mathbf{b})$. If $\|\mathbf{q}_{k+1}\|$ is below a certain tolerance, stop and return H and Q . Otherwise, normalize the new basis vector new \mathbf{q}_{k+1} and continue to the next iteration.

Algorithm 1 The Arnoldi iteration. This algorithm accepts a square matrix A and a starting vector \mathbf{b} . It iterates k times or until the norm of the next vector in the iteration is less than tol . The algorithm returns an upper Hessenberg H and an orthonormal Q such that $H = Q^H A Q$.

```

1: procedure ARNOLDI( $\mathbf{b}, A, k, \text{tol}$ )
2:    $Q \leftarrow \text{empty}(\text{size}(\mathbf{b}), k + 1)$                                  $\triangleright$  Some initialization steps
3:    $H \leftarrow \text{zeros}(k + 1, k)$ 
4:    $Q_{:,0} \leftarrow \mathbf{b} / \|\mathbf{b}\|_2$ 
5:   for  $j = 0 \dots k - 1$  do                                          $\triangleright$  Perform the actual iteration.
6:      $Q_{:,j+1} \leftarrow A(Q_{:,j})$ 
7:     for  $i = 0 \dots j$  do                                          $\triangleright$  Modified Gram-Schmidt.
8:        $H_{i,j} \leftarrow Q_{:,i}^H Q_{:,j+1}$ 
9:        $Q_{:,j+1} \leftarrow Q_{:,j+1} - H_{i,j} Q_{:,i}$ 
10:       $H_{j+1,j} \leftarrow \|Q_{:,j+1}\|_2$                                           $\triangleright$  Set subdiagonal element of  $H$ .
11:      if  $|H_{j+1,j}| < \text{tol}$  then                                          $\triangleright$  Stop if  $\|Q_{:,j+1}\|_2$  is small enough.
12:        return  $H_{:,j+1}, Q_{:,j+1}$ 
13:         $Q_{:,j+1} \leftarrow Q_{:,j+1} / H_{j+1,j}$                                           $\triangleright$  Normalize  $\mathbf{q}_{j+1}$ .
14:    return  $H_{:-1,:}, Q$                                           $\triangleright$  Return  $H_k$  and  $Q$ .

```

ACHTUNG!

If the starting vector \mathbf{x} is an eigenvector of A with corresponding eigenvalue λ , then by definition $\mathcal{K}_k(A, \mathbf{x}) = \text{span}\{\mathbf{x}, \lambda\mathbf{x}, \lambda^2\mathbf{x}, \dots, \lambda^k\mathbf{x}\}$, which is equal to the span of \mathbf{x} . So, when \mathbf{x} is normalized with $\mathbf{q}_1 = \mathbf{x} / \|\mathbf{x}\|$, $\mathbf{q}_2 = A\mathbf{q}_1 = \lambda\mathbf{q}_1$.

The vector \mathbf{q}_2 is supposed to be the next vector in the orthonormal basis for $\mathcal{K}_k(A, \mathbf{x})$, but it is not linearly independent of \mathbf{q}_1 . In fact, \mathbf{q}_1 already spans $\mathcal{K}_k(A, \mathbf{x})$. Hence, the Gram-Schmidt process fails and results in a [ZeroDivisionError](#) or an extremely early termination of the algorithm. A similar phenomenon may occur if the starting vector \mathbf{x} is contained in a proper invariant subspace of A .

Arnoldi Iteration on Linear Operators

A major strength of the Arnoldi iteration is that it can run on a linear operator, even without knowing the matrix representation of the operator. If L is some linear function, then we can modify the pseudocode above by replacing $AQ_{:,j}$ with $A_{mul}(Q_{:,j})$. This makes it possible to find the eigenvalues of an arbitrary linear transformation.

Problem 1. Write a function that accepts a starting vector \mathbf{b} for the Arnoldi Iteration, a function handle L that describes a linear operator, the number of times n to perform the iteration, and a tolerance tol that defaults to 10^{-8} . Use Algorithm 1 to implement the Arnoldi Iteration with these parameters. Return the upper Hessenberg matrix H and the orthonormal matrix Q from the iteration.

Consider the following implementation details.

1. Since H and Q will eventually hold complex numbers, initialize them as complex arrays (e.g., $\mathbf{A} = \text{np.empty}((3,3), \text{dtype=np.complex128})$).
2. This function can be tested on a matrix A by passing in $\mathbf{A}.\text{dot}$ for a linear operator.
3. Remember to use complex inner products. Here is an example of how to evaluate $A^H A$:

```
b = A.conj() @ B
```

Test your function by comparing the resulting H with $Q^H A Q$.

Finding Eigenvalues Using the Arnoldi Iteration

Let A be an $n \times n$ matrix. Let Q_k be the matrix whose columns $\mathbf{q}_1, \dots, \mathbf{q}_k$ are the orthonormal basis for $\mathcal{K}_m(A, \mathbf{x})$ generated by the Arnoldi algorithm, and let H_k be the $k \times k$ upper Hessenburg matrix defined at the k th stage of the algorithm. Then these matrices satisfy

$$H_k = Q_k^H A Q_k. \quad (16.1)$$

If $k < n$, then H_k is a low-rank approximation to A and the eigenvalues of H_k may be used as approximations for the eigenvalues of A . The eigenvalues of H_k are called *Ritz Values*, and we will later show that they converge quickly to the largest eigenvalues of A .

Problem 2. Write a function that accepts a function handle L that describes a linear operator, the dimension of the space dim that the linear operator works on, the number of times k to perform the Arnoldi Iteration, and the number of Ritz values n to return. Use the previous implementation of the Arnoldi Iteration and an eigenvalue function such as `scipy.linalg.eigs()` to compute the largest Ritz values of the given operator. Return the n largest Ritz values.

One application of the Arnoldi iteration is to find the eigenvalues of linear operators that are too large to store in memory. For example, if an operator acts on a vector $\mathbf{x} \in \mathbb{C}^{2^{20}}$, then its matrix representation contains 2^{40} complex values. Storing such a matrix would require 64 terabytes of memory!

An example of such an operator is the Fast Fourier Transform, cited by SIAM as one of the top algorithms of the century [Cip00]. The Fast Fourier Transform is used very commonly in signal processing.

Problem 3. The four largest eigenvalues of the Fast Fourier Transform are known to be $\{-\sqrt{n}, \sqrt{n}, -i\sqrt{n}, i\sqrt{n}\}$ where n is the dimension of the space on which the transform acts.

Use your function from Problem 2 to approximate the eigenvalues of the Fast Fourier Transform. Set $k = 10$ and $\text{dim} = 2^{20}$. For the argument L , use the `scipy.fftpack.fft()`.

The Arnoldi iteration for finding eigenvalues is implemented in a Fortran library called ARPACK. Scipy interfaces with the Arnoldi iteration in this library via the function `scipy.sparse.linalg.eigs()`. This function has many more options than the implementation we wrote in Problem 2. In this example, the keyword argument `k=5` specifies that we want five Ritz values. Note that even though this function comes from the `sparse` library in Scipy, we can still call it on regular Numpy arrays.

```
>>> from scipy.sparse import linalg as spla
>>> B = np.random.random((100, 100))
>>> spla.eigs(B, k=5, return_eigenvectors=False)
array([-1.15577072-2.59438308j, -2.63675878-1.09571889j,
       -2.63675878+1.09571889j, -3.00915592+0.j, 50.14472893+0.j])
```

Convergence

As more iterations of the Arnoldi method are performed, our approximations are of higher rank. Consequently, the Ritz values become more accurate approximations to the eigenvalues of the linear operator.

This technique converges quickly to eigenvalues whose magnitude is distinctly larger than the rest. For example, matrices with random entries tend to have one eigenvalue of distinctly greatest magnitude. Convergence of the Ritz values for such a matrix is plotted in Figure 16.1a.

However, Ritz values converge more slowly for matrices with random eigenvalues. Figure 16.1b plots convergence of the Ritz values for a matrix with eigenvalues uniformly distributed in $[0, 1]$.

Problem 4. Write a function that accepts a linear operator A , the number of Ritz values to plot n , and the the number of times to perform the Arnoldi iteration `iters`. Use these parameters to create a plot of the absolute error between the largest Ritz values of A and the largest eigenvalues of A .

1. Find n eigenvalues of A of largest magnitude. Store these in order.
2. Create an empty array to store the relative errors for every $k = 0, 1, \dots, \text{iters}$.
 - (a) Use your Ritz function to find the n largest Ritz values of the operator. Note that for small k , the matrix H_k may not have this many eigenvalues. Due to this, the graphs of some eigenvalues have to begin after a few iterations.
 - (b) Store the absolute error between the eigenvalues of A and the Ritz values of H . Make sure that the errors are stored in the correct order.
3. Iteratively plot the errors for each eigenvalue with the range of the iterations.

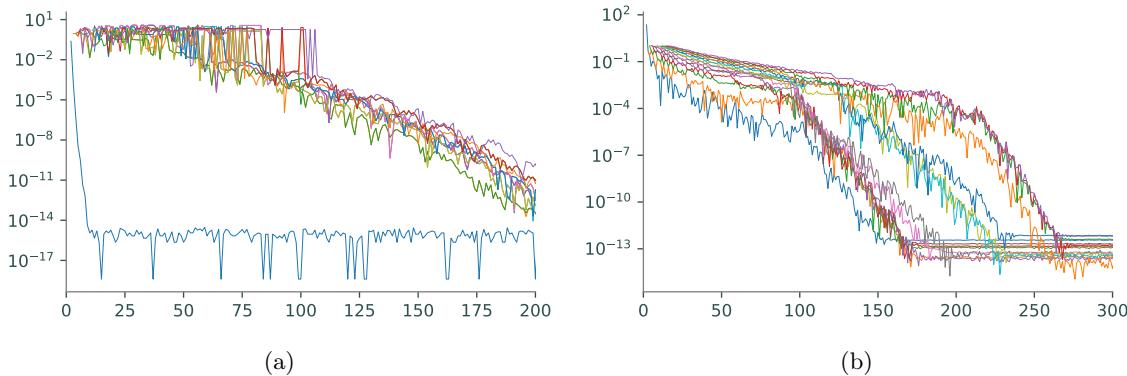

Figure 16.1: These plots show the relative error of the ritz values as approximations to the eigenvalues of a matrix. The figure on the left plots the largest 15 Ritz values for a 500×500 matrix with random entries and demonstrates that the largest eigenvalue (the blue line) converges after 20 iterations. The figure at right plots the largest 15 Ritz values for a 500×500 matrix with uniformly distributed eigenvalues in $[0, 1]$ and demonstrates that all the eigenvalues take from 150 to 250 iterations to converge.

Hints: If $\tilde{\mathbf{x}}$ is an approximation to \mathbf{x} , then the *absolute error* in the approximation is $\|\mathbf{x} - \tilde{\mathbf{x}}\|$.

Sort your eigenvalues from greatest to least. An example of how to do this is included:

```
# Evaluate the eigenvalues
eigvalues = la.eig(A)[0]
# Sort them from greatest to least (use np.abs to account for complex ←
# parts)
eigvalues = eigvalues[np.sort(np.abs(eigvalues))[:-1]]
```

In addition, remember that certain eigenvalues of H will not appear until we are computing enough iterations in the Arnoldi algorithm. As a result, we will have to begin the graphs of several eigenvalues after we are computing sufficient iterations of the algorithm.

Run your function on these examples. The plots should be fairly similar to Figures 16.1b and 16.1a.

```
>>> A = np.random.rand(300, 300)
>>> plot_ritz(a, 10, 175)

>>> # A matrix with uniformly distributed eigenvalues
>>> d = np.diag(np.random.rand(300))
>>> B = A @ d @ la.inv(A)
>>> plot_ritz(B, 10, 175)
```

Additional Material

The Lanczos Iteration

The Lanczos iteration is a version of the Arnoldi iteration that is optimized to operate on symmetric matrices. If A is symmetric, then (16.1) shows that H_k is symmetric and hence tridiagonal. This leads to two simplifications of the Arnoldi algorithm.

First, we have $0 = H_{k,n} = \langle \mathbf{q}_k, A\mathbf{q}_n \rangle$ for $k \leq n - 2$; i.e., $A\mathbf{q}_n$ is orthogonal to $\mathbf{q}_1, \dots, \mathbf{q}_{n-2}$. Thus, if the goal is only to compute H_k (say to find the Ritz values), then we only need to store the two most recently computed columns of Q . Second, the data of H_k can also be stored in two vectors, one containing the main diagonal and one containing the first subdiagonal of H_k (by symmetry, the first superdiagonal equals the first subdiagonal of H_k).

Algorithm 2 The Lanczos Iteration. This algorithm operates on a vector \mathbf{b} of length n and an $n \times n$ symmetric matrix A . It iterates k times or until the norm of the next vector in the iteration is less than tol . It returns two vectors \mathbf{x} and \mathbf{y} that respectively contain the main diagonal and first subdiagonal of the current Hessenberg approximation.

```

1: procedure LANCZOS( $\mathbf{b}, A, k, tol$ )
2:    $\mathbf{q}_0 \leftarrow \text{zeros}(\text{size}(\mathbf{b}))$                                  $\triangleright$  Some initialization
3:    $\mathbf{q}_1 \leftarrow \mathbf{b} / \|\mathbf{b}\|_2$ 
4:    $\mathbf{x} \leftarrow \text{empty}(k)$ 
5:    $\mathbf{y} \leftarrow \text{empty}(k)$ 
6:   for  $i = 0 \dots k - 1$  do                                          $\triangleright$  Perform the iteration.
7:      $\mathbf{z} \leftarrow A\mathbf{q}_1$                                                $\triangleright$   $\mathbf{z}$  is a temporary vector to store  $\mathbf{q}_{i+1}$ .
8:      $\mathbf{x}[i] \leftarrow \mathbf{q}_1^\top \mathbf{z}$                                       $\triangleright$   $\mathbf{q}_1$  is used to store the previous  $\mathbf{q}_i$ .
9:      $\mathbf{z} \leftarrow \mathbf{z} - \mathbf{x}[i]\mathbf{q}_1 + \mathbf{y}[i-1]\mathbf{q}_0$            $\triangleright$   $\mathbf{q}_0$  is used to store  $\mathbf{q}_{i-1}$ .
10:     $\mathbf{y}[i] = \|\mathbf{z}\|_2$                                                $\triangleright$  Initialize  $\mathbf{y}[i]$ .
11:    if  $\mathbf{y}[i] < tol$  then                                          $\triangleright$  Stop if  $\|\mathbf{q}_{i+1}\|_2$  is too small.
12:      return  $\mathbf{x}[:, i+1], \mathbf{y}[:, i]$ 
13:     $\mathbf{z} = \mathbf{z}/\mathbf{y}[i]$ 
14:     $\mathbf{q}_0, \mathbf{q}_1 = \mathbf{q}_1, \mathbf{z}$                                           $\triangleright$  Store new  $\mathbf{q}_{i+1}$  and  $\mathbf{q}_i$  on top of  $\mathbf{q}_1$  and  $\mathbf{q}_0$ .
15:  return  $\mathbf{x}, \mathbf{y}[:, -1]$ 

```

As it is described in Algorithm 2, the Lanczos iteration is not stable. Roundoff error may cause the \mathbf{q}_i to be far from orthogonal. In fact, it is possible for the \mathbf{q}_i to be so adulterated by roundoff error that they are no longer linearly independent.

There are modified versions of the Lanczos iteration that are numerically stable. One of these, the Implicitly Restarted Lanczos Method, is found in SciPy as `scipy.sparse.linalg.eigsh()`.

17

GMRES

Lab Objective: *The Generalized Minimal Residuals (GMRES) algorithm is an iterative Krylov subspace method for efficiently solving large linear systems. In this lab we implement the basic GMRES algorithm, then make an improvement by using restarts. We then discuss the convergence of the algorithm and its relationship with the eigenvalues of a linear system. Finally, we introduce SciPy's version of GMRES.*

The GMRES Algorithm

GMRES is an iterative method that uses Krylov subspaces to reduce a high-dimensional problem to a sequence of smaller dimensional problems. Let A be an invertible $m \times m$ matrix and let \mathbf{b} be a vector of length m . Let $\mathcal{K}_n(A, \mathbf{b})$ be the order- n Krylov subspace generated by A and \mathbf{b} . Instead of solving the system $A\mathbf{x} = \mathbf{b}$ directly, GMRES uses least squares to find $\mathbf{x}_n \in \mathcal{K}_n$ that minimizes the residual $r_n = \|\mathbf{b} - A\mathbf{x}_n\|_2$. The algorithm terminates when this residual is smaller than some predetermined value. In many situations, this happens when n is much smaller than m .

The GMRES algorithm uses the Arnoldi iteration for numerical stability. The Arnoldi iteration produces H_n , an $(n+1) \times n$ upper Hessenberg matrix, and Q_n , a matrix whose columns make up an orthonormal basis of $\mathcal{K}_n(A, \mathbf{b})$, such that $AQ_n = Q_{n+1}H_n$. The GMRES algorithm finds the vector \mathbf{x}_n which minimizes the norm $\|\mathbf{b} - A\mathbf{x}_n\|_2$, where $\mathbf{x}_n = Q_n\mathbf{y}_n + \mathbf{x}_0$ for some $\mathbf{y}_n \in \mathbb{R}^n$. Since the columns of Q_n are orthonormal, the residual can be equivalently computed as

$$\|\mathbf{b} - A\mathbf{x}_n\|_2 = \|Q_{n+1}(\beta\mathbf{e}_1 - H_n\mathbf{y}_n)\|_2 = \|H_n\mathbf{y}_n - \beta\mathbf{e}_1\|_2. \quad (17.1)$$

Here \mathbf{e}_1 is the vector $[1, 0, \dots, 0]^\top$ of length $n+1$ and $\beta = \|\mathbf{b} - A\mathbf{x}_0\|_2$, where \mathbf{x}_0 is an initial guess of the solution. Thus, to minimize $\|\mathbf{b} - A\mathbf{x}_n\|_2$, the right side of (17.1) can be minimized, and \mathbf{x}_n can be computed as $\mathbf{x}_n = Q_n\mathbf{y}_n + \mathbf{x}_0$.

Algorithm 1 The GMRES algorithm. This algorithm operates on a vector \mathbf{b} and a linear operator A . It iterates k times or until the residual is less than tol , returning an approximate solution to $A\mathbf{x} = \mathbf{b}$ and the error in this approximation.

```

1: procedure GMRES( $A, \mathbf{b}, \mathbf{x}_0, k, \text{tol}$ )
2:    $Q \leftarrow \text{empty}(\text{size}(\mathbf{b}), k + 1)$                                  $\triangleright$  Initialization.
3:    $H \leftarrow \text{zeros}(k + 1, k)$ 
4:    $r_0 \leftarrow \mathbf{b} - A(\mathbf{x}_0)$ 
5:    $Q_{:,0} = r_0 / \|r_0\|_2$ 
6:   for  $j = 0 \dots k - 1$  do                                          $\triangleright$  Perform the Arnoldi iteration.
7:      $Q_{:,j+1} \leftarrow A(Q_{:,j})$ 
8:     for  $i = 0 \dots j$  do
9:        $H_{i,j} \leftarrow Q_{:,i}^T Q_{:,j+1}$ 
10:       $Q_{:,j+1} \leftarrow Q_{:,j+1} - H_{i,j} Q_{:,i}$ 
11:       $H_{j+1,j} \leftarrow \|Q_{:,j+1}\|_2$ 
12:      if  $|H_{j+1,j}| > \text{tol}$  then                                      $\triangleright$  Avoid dividing by zero.
13:         $Q_{:,j+1} \leftarrow Q_{:,j+1} / H_{j+1,j}$ 
14:       $\mathbf{y} \leftarrow \text{least squares solution to } \|H_{:,j+1} \mathbf{x} - \beta e_1\|_2$      $\triangleright \beta$  and  $e_1$  as in (17.1).
15:       $\text{res} \leftarrow \|H_{:,j+1} \mathbf{y} - \beta e_1\|_2$ 
16:      if  $\text{res} < \text{tol}$  then
17:        return  $Q_{:,j+1} \mathbf{y} + \mathbf{x}_0, \text{res}$ 
18:    return  $Q_{:,j+1} \mathbf{y} + \mathbf{x}_0, \text{res}$ 

```

Problem 1. Write a function that accepts a matrix A , a vector \mathbf{b} , and an initial guess \mathbf{x}_0 , a maximum number of iterations k defaulting to 100, and a stopping tolerance tol that defaults to 10^{-8} . Use Algorithm 1 to approximate the solution to $A\mathbf{x} = \mathbf{b}$ using the GMRES algorithm. Return the approximate solution and the residual at the approximate solution.

You may assume that A and \mathbf{b} only have real entries. Use `scipy.linalg.lstsq()` to solve the least squares problem. Be sure to read the documentation so that you understand what the function returns.

Compare your function to the following code.

```

>>> A = np.array([[1, 0, 0], [0, 2, 0], [0, 0, 3]])
>>> b = np.array([1, 4, 6])
>>> x0 = np.zeros(b.size)
>>> gmres(A, b, x0, k=100, tol=1e-8)
(array([ 1.,  2.,  2.]), 7.174555448775421e-16)

```

Convergence of GMRES

One of the most important characteristics of GMRES is that it will always arrive at an exact solution (if one exists). At the n -th iteration, GMRES computes the best approximate solution to $A\mathbf{x} = \mathbf{b}$ for $\mathbf{x}_n \in \mathcal{K}_n$. If A is full rank, then $\mathcal{K}_m = \mathbb{F}^m$, so the m th iteration will always return an exact answer. Sometimes, the exact solution $\mathbf{x} \in \mathcal{K}_n$ for some $n < m$, in this case x_n is an exact solution. In either case, the algorithm is convergent after n steps if the n th residual is sufficiently small.

The rate of convergence of GMRES depends on the eigenvalues of A .

Problem 2. Add a keyword argument `plot` defaulting to `False` to your function from Problem 1. If `plot=True`, keep track of the residuals at each step of the algorithm. At the end of the iteration, before returning the approximate solution and its residual error, create a figure with two subplots.

1. Make a scatter plot of the eigenvalues of A on the complex plane.
2. Plot the residuals versus the iteration counts using a log scale on the y -axis (use `ax.semilogy()`).

Problem 3. Use your function from Problem 2 to investigate how the convergence of GMRES relates to the eigenvalues of a matrix as follows. Define an $m \times m$ matrix

$$A_n = nI + P,$$

where I is the identity matrix and P is an $m \times m$ matrix with entries taken from a random normal distribution with mean 0 and standard deviation $1/(2\sqrt{m})$. Call your function from Problem 2 on A_n for $n = -4, -2, 0, 2, 4$. Use $m = 200$, let \mathbf{b} be an array of all ones, and let $\mathbf{x}_0 = \mathbf{0}$.

Use `np.random.normal()` to create the matrix P . When analyzing your results, pay special attention to the clustering of the eigenvalues in relation to the origin. Compare your results with $n = 2$, $m = 200$ to Figure 17.1.

Ideas for this problem were taken from Example 35.1 on p. 271 of [TB97].

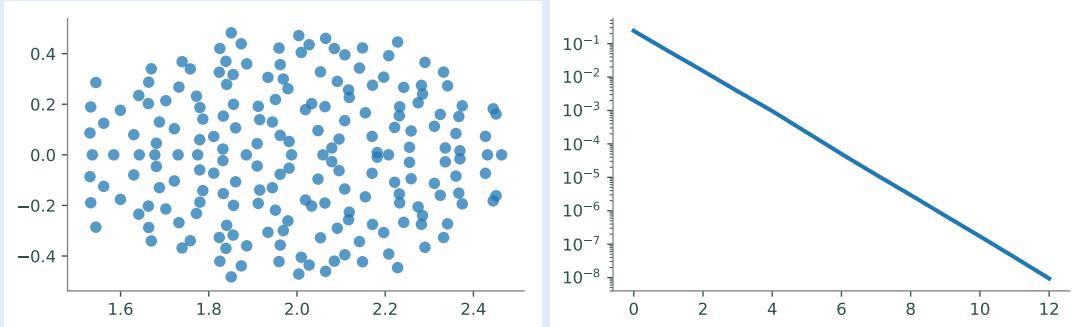

Figure 17.1: On the left, the eigenvalues of the matrix A_2 defined in Problem 3. On the right, the rapid convergence of the GMRES algorithm on A_2 with starting vector $\mathbf{b} = (1, 1, \dots, 1)$.

GMRES with Restarts

The first few iterations of GMRES have low spatial and temporal complexity. However, as k increases, the k th iteration of GMRES becomes more expensive temporally and spatially. In fact, computing the k th iteration of GMRES for very large k can be prohibitively complex.

This issue is addressed by using GMRES(k), or GMRES with restarts. When k becomes large, this algorithm restarts GMRES with an improved initial guess. The new initial guess is taken to be the vector that was found upon termination of the last GMRES iteration run. The algorithm GMRES(k) will always have manageable spatial and temporal complexity, but it is less reliable than GMRES. If the true solution \mathbf{x} to $A\mathbf{x} = \mathbf{b}$ is nearly orthogonal to the Krylov subspaces $\mathcal{K}_n(A, \mathbf{b})$ for $n \leq k$, then GMRES(k) could converge very slowly or not at all.

Problem 4. Write a function that implements GMRES with restarts as follows.

1. Perform the GMRES algorithm for a maximum of k iterations.
2. If the desired tolerance was reached, terminate the algorithm. If not, repeat step 1 using x_k from the previous GMRES algorithm as a new initial guess x_0 .
3. Repeat step 2 until the desired tolerance has been obtained or until a given maximum number of restarts has been reached.

Your function should accept all of the same inputs as the function you wrote in Problem 1 with the exception of k , which will now denote the number of iterations before restart (defaults to 5), and an additional parameter `restarts` which denotes the maximum number of restarts before termination (defaults to 50).

GMRES in SciPy

The GMRES algorithm is implemented in SciPy as the function `scipy.sparse.linalg.gmres()`. Here we use this function to solve $A\mathbf{x} = \mathbf{b}$ where A is a random 300×300 matrix and \mathbf{b} is a random vector.

```
>>> import numpy as np
>>> from scipy import sparse
>>> from scipy.sparse import linalg as spla

>>> A = np.random.rand(300, 300)
>>> b = np.random(300)
>>> x, info = spla.gmres(A, b)
>>> print(info)
3000
```

The function outputs two objects: the approximate solution \mathbf{x} and an integer `info` which gives information about the convergence of the algorithm. If `info=0` then convergence occurred; if `info` is positive then it equals the number of iterations performed. In the previous case, the function performed 3000 iterations of GMRES before returning the approximate solution \mathbf{x} . The following code verifies how close the computed value was to the exact solution.

```
>>> la.norm((A @ x) - b)
4.744196381683801
```

A better approximation can be obtained using GMRES with restarts.

```
# Restart after 1000 iterations.  
>>> x, info = spla.gmres(A, b, restart=1000)  
>>> info  
0  
>>> la.norm((A @ x) - b)  
1.0280404494143551e-12
```

This time, the returned approximation \mathbf{x} is about as close to a true solution as can be expected.

Problem 5. Plot the runtimes of your implementations of GMRES from Problems 1 and 4 and `scipy.sparse.linalg.gmres()` use the default tolerance and `restart=1000` with different matrices. Use the $m \times m$ matrix P with $m = 25, 50, \dots, 200$ and with entries taken from a random normal distribution with mean 0 and standard deviation $1/(2\sqrt{m})$. Use a vector of ones for \mathbf{b} and a vector of zeros for \mathbf{x}_0 . Use a single figure for all plots, plot the runtime on the y -axis and m on the x -axis.

NumPy Visual Guide

Lab Objective: NumPy operations can be difficult to visualize, but the concepts are straightforward. This appendix provides visual demonstrations of how NumPy arrays are used with slicing syntax, stacking, broadcasting, and axis-specific operations. Though these visualizations are for 1- or 2-dimensional arrays, the concepts can be extended to n -dimensional arrays.

Data Access

The entries of a 2-D array are the rows of the matrix (as 1-D arrays). To access a single entry, enter the row index, a comma, and the column index. Remember that indexing begins with 0.

$$A[0] = \begin{bmatrix} \times & \times & \times & \times & \times \\ \times & \times & \times & \times & \times \\ \times & \times & \times & \times & \times \\ \times & \times & \times & \times & \times \end{bmatrix} \quad A[2,1] = \begin{bmatrix} \times & \times & \times & \times & \times \\ \times & \times & \times & \times & \times \\ \times & \times & \times & \times & \times \\ \times & \times & \times & \times & \times \end{bmatrix}$$

Slicing

A lone colon extracts an entire row or column from a 2-D array. The syntax $[a:b]$ can be read as “the a th entry up to (but not including) the b th entry.” Similarly, $[a:]$ means “the a th entry to the end” and $[:b]$ means “everything up to (but not including) the b th entry.”

$$A[1] = A[1,:] = \begin{bmatrix} \times & \times & \times & \times & \times \\ \times & \times & \times & \times & \times \\ \times & \times & \times & \times & \times \\ \times & \times & \times & \times & \times \end{bmatrix} \quad A[:,2] = \begin{bmatrix} \times & \times & \times & \times & \times \\ \times & \times & \times & \times & \times \\ \times & \times & \times & \times & \times \\ \times & \times & \times & \times & \times \end{bmatrix}$$

$$A[1:,:2] = \begin{bmatrix} \times & \times & \times & \times & \times \\ \times & \times & \times & \times & \times \\ \times & \times & \times & \times & \times \\ \times & \times & \times & \times & \times \end{bmatrix} \quad A[1:-1,1:-1] = \begin{bmatrix} \times & \times & \times & \times & \times \\ \times & \times & \times & \times & \times \\ \times & \times & \times & \times & \times \\ \times & \times & \times & \times & \times \end{bmatrix}$$

Stacking

`np.hstack()` stacks sequence of arrays horizontally and `np.vstack()` stacks a sequence of arrays vertically.

$$A = \begin{bmatrix} \times & \times & \times \\ \times & \times & \times \\ \times & \times & \times \end{bmatrix}$$

$$B = \begin{bmatrix} * & * & * \\ * & * & * \\ * & * & * \end{bmatrix}$$

$$\text{np.hstack}((A, B, A)) = \begin{bmatrix} \times & \times & \times & * & * & * & \times & \times & \times \\ \times & \times & \times & * & * & * & \times & \times & \times \\ \times & \times & \times & * & * & * & \times & \times & \times \end{bmatrix}$$

$$\text{np.vstack}((A, B, A)) = \begin{bmatrix} \times & \times & \times \\ \times & \times & \times \\ \times & \times & \times \\ * & * & * \\ * & * & * \\ * & * & * \\ \times & \times & \times \\ \times & \times & \times \\ \times & \times & \times \end{bmatrix}$$

Because 1-D arrays are flat, `np.hstack()` concatenates 1-D arrays and `np.vstack()` stacks them vertically. To make several 1-D arrays into the columns of a 2-D array, use `np.column_stack()`.

$$x = [\times \quad \times \quad \times \quad \times]$$

$$y = [* \quad * \quad * \quad *]$$

$$\text{np.hstack}((x, y, x)) = [\times \quad \times \quad \times \quad \times \quad * \quad * \quad * \quad * \quad \times \quad \times \quad \times \quad \times]$$

$$\text{np.vstack}((x, y, x)) = \begin{bmatrix} \times & \times & \times & \times \\ * & * & * & * \\ \times & \times & \times & \times \end{bmatrix}$$

$$\text{np.column_stack}((x, y, x)) = \begin{bmatrix} \times & * & \times \\ \times & * & \times \\ \times & * & \times \\ \times & * & \times \end{bmatrix}$$

The functions `np.concatenate()` and `np.stack()` are more general versions of `np.hstack()` and `np.vstack()`, and `np.row_stack()` is an alias for `np.vstack()`.

Broadcasting

NumPy automatically aligns arrays for component-wise operations whenever possible. See <http://docs.scipy.org/doc/numpy/user/basics.broadcasting.html> for more in-depth examples and broadcasting rules.

$$A = \begin{bmatrix} 1 & 2 & 3 \\ 1 & 2 & 3 \\ 1 & 2 & 3 \end{bmatrix} \quad x = [10 \quad 20 \quad 30]$$

$$A + x = \begin{bmatrix} 1 & 2 & 3 \\ 1 & 2 & 3 \\ 1 & 2 & 3 \\ + \\ 10 & 20 & 30 \end{bmatrix} = \begin{bmatrix} 11 & 22 & 33 \\ 11 & 22 & 33 \\ 11 & 22 & 33 \end{bmatrix}$$

$$A + x.reshape((1, -1)) = \begin{bmatrix} 1 & 2 & 3 \\ 1 & 2 & 3 \\ 1 & 2 & 3 \end{bmatrix} + \begin{bmatrix} 10 \\ 20 \\ 30 \end{bmatrix} = \begin{bmatrix} 11 & 12 & 13 \\ 21 & 22 & 23 \\ 31 & 32 & 33 \end{bmatrix}$$

Operations along an Axis

Most array methods have an `axis` argument that allows an operation to be done along a given axis. To compute the sum of each column, use `axis=0`; to compute the sum of each row, use `axis=1`.

$$A = \begin{bmatrix} 1 & 2 & 3 & 4 \\ 1 & 2 & 3 & 4 \\ 1 & 2 & 3 & 4 \\ 1 & 2 & 3 & 4 \end{bmatrix}$$

$$A.sum(axis=0) = \left[\begin{array}{c|c|c|c} 1 & 2 & 3 & 4 \\ \hline 1 & 2 & 3 & 4 \\ 1 & 2 & 3 & 4 \\ 1 & 2 & 3 & 4 \end{array} \right] = [4 \quad 8 \quad 12 \quad 16]$$

$$A.sum(axis=1) = \left[\begin{array}{cccc} 1 & 2 & 3 & 4 \\ \hline 1 & 2 & 3 & 4 \\ 1 & 2 & 3 & 4 \\ \hline 1 & 2 & 3 & 4 \end{array} \right] = [10 \quad 10 \quad 10 \quad 10]$$

B

Matplotlib Syntax and Customization Guide

Lab Objective: *The documentation for Matplotlib can be a little difficult to maneuver and basic information is sometimes difficult to find. This appendix condenses and demonstrates some of the more applicable and useful information on plot customizations. It is not intended to be read all at once, but rather to be used as a reference when needed. For an interative introduction to Matplotlib, see the Introduction to Matplotlib lab in Python Essentials. For more details on any specific function, refer to the Matplotlib documentation at <https://matplotlib.org/>.*

Matplotlib Interface

Matplotlib plots are made in a `Figure` object that contains one or more `Axes`, which themselves contain the graphical plotting data. Matplotlib provides two ways to create plots:

1. Call plotting functions directly from the module, such as `plt.plot()`. This will create the plot on whichever `Axes` is currently active.
2. Call plotting functions from an `Axes` object, such as `ax.plot()`. This is particularly useful for complicated plots and for animations.

Table B.1 contains a summary of functions that are used for managing `Figure` and `Axes` objects.

Function	Description
<code>add_subplot()</code>	Add a single subplot to the current figure
<code>axes()</code>	Add an axes to the current figure
<code>clf()</code>	Clear the current figure
<code>figure()</code>	Create a new figure or grab an existing figure
<code>gca()</code>	Get the current axes
<code>gcf()</code>	Get the current figure
<code>subplot()</code>	Add a single subplot to the current figure
<code>subplots()</code>	Create a figure and add several subplots to it

Table B.1: Basic functions for managing plots.

`Axes` objects are usually managed through the functions `plt.subplot()` and `plt.subplots()`. The function `subplot()` is used as `plt.subplot(nrows, ncols, plot_number)`. Note that if the inputs for `plt.subplot()` are all integers, the commas between the entries can be omitted. For example, `plt.subplot(3,2,2)` can be shortened to `plt.subplot(322)`.

The function `subplots()` is used as `plt.subplots(nrows, ncols)`, and returns a `Figure` object and an array of `Axes`. This array has the shape `(nrows, ncols)`, and can be accessed as any other array. Figure B.1 demonstrates the layout and indexing of subplots.

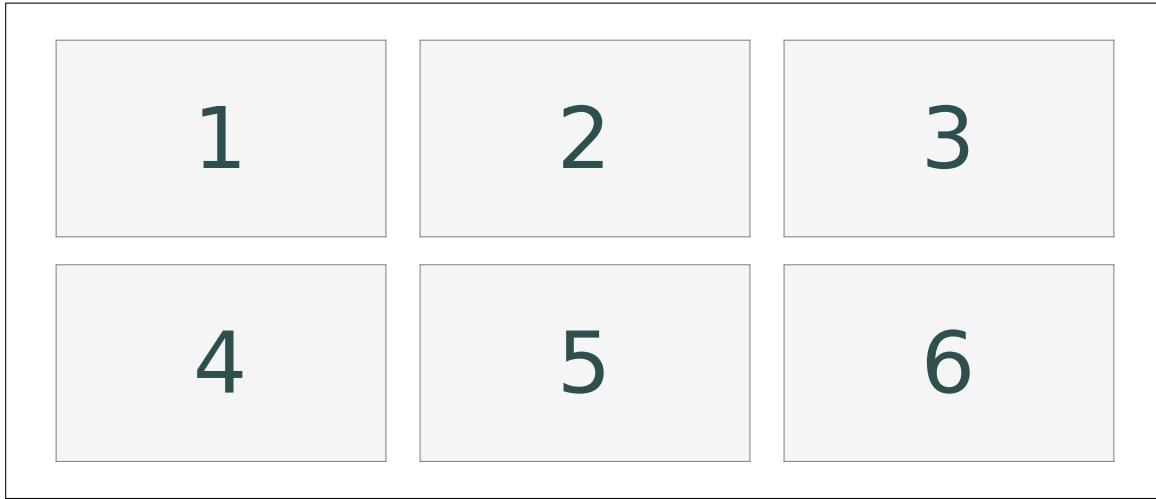

Figure B.1: The layout of subplots with `plt.subplot(2,3,i)` (2 rows, 3 columns), where `i` is the index pictured above. The outer border is the figure that the axes belong to.

The following example demonstrates three equivalent ways of producing a figure with two subplots, arranged next to each other in one row:

```
>>> x = np.linspace(-5, 5, 100)

# 1. Use plt.subplot() to switch the current axes.
>>> plt.subplot(121)
>>> plt.plot(x, 2*x)
>>> plt.subplot(122)
>>> plt.plot(x, x**2)

# 2. Use plt.subplot() to explicitly grab the two subplot axes.
>>> ax1 = plt.subplot(121)
>>> ax1.plot(x, 2*x)
>>> ax2 = plt.subplot(122)
>>> ax2.plot(x, x**2)

# 3. Use plt.subplots() to get the figure and all subplots simultaneously.
>>> fig, axes = plt.subplots(1, 2)
>>> axes[0].plot(x, 2*x)
>>> axes[1].plot(x, x**2)
```

ACHTUNG!

Be careful not to mix up the following similarly-named functions:

1. `plt.axes()` creates a new place to draw on the figure, while `plt.axis()` or `ax.axis()` sets properties of the *x*- and *y*-axis in the current axes, such as the *x* and *y* limits.
2. `plt.subplot()` (singular) returns a single subplot belonging to the current figure, while `plt.subplots()` (plural) creates a new figure and adds a collection of subplots to it.

Plot Customization

Styles

Matplotlib has a number of built-in styles that can be used to set the default appearance of plots. These can be used via the function `plt.style.use()`; for instance, `plt.style.use("seaborn")` will have Matplotlib use the "seaborn" style for all plots created afterwards. A list of built-in styles can be found at https://matplotlib.org/stable/gallery/style_sheets/style_sheets_reference.html.

The style can also be changed only temporarily using `plt.style.context()` along with a `with` block:

```
with plt.style.context('dark_background'):
    # Any plots created here use the new style
    plt.subplot(1,2,1)
    plt.plot(x, y)
    #
# Plots created here are unaffected
plt.subplot(1,2,2)
plt.plot(x, y)
```

Plot layout

Axis properties

Table B.2 gives an overview of some of the functions that may be used to configure the axes of a plot.

The functions `xlim()`, `ylim()`, and `axis()` are used to set one or both of the *x* and *y* ranges of the plot. `xlim()` and `ylim()` each accept two arguments, the lower and upper bounds, or a single list of those two numbers. `axis()` accepts a single list consisting, in order, of `xmin`, `xmax`, `ymin`, `ymax`. Passing `None` instead of one of the numbers to any of these functions will make it not change the corresponding value from what it was. Each of these functions can also be called without any arguments, in which case it will return the current bounds. Note that `axis()` can also be called directly on an `Axes` object, while `xlim()` and `ylim()` cannot.

`axis()` also can be called with a string as its argument, which has several options. The most common is `axis('equal')`, which makes the scale of the *x*- and *y*-scales equal (i.e. makes circles circular).

Function	Description
<code>axis()</code>	set the x - and y -limits of the plot
<code>grid()</code>	add gridlines
<code>xlim()</code>	set the limits of the x -axis
<code>ylim()</code>	set the limits of the y -axis
<code>xticks()</code>	set the location of the tick marks on the x -axis
<code>yticks()</code>	set the location of the tick marks on the y -axis
<code>xscale()</code>	set the scale type to use on the x -axis
<code>yscale()</code>	set the scale type to use on the y -axis
<code>ax.spines[side].set_position()</code>	set the location of the given spine
<code>ax.spines[side].set_color()</code>	set the color of the given spine
<code>ax.spines[side].set_visible()</code>	set whether a spine is visible

Table B.2: Some functions for changing axis properties. `ax` is an `Axes` object.

To use a logarithmic scale on an axis, the functions `xscale("log")` and `yscale("log")` can be used.

The functions `xticks()` and `yticks()` accept a list of tick positions, which the ticks on the corresponding axis are set to. Generally, this works the best when used with `np.linspace()`. This function also optionally accepts a second argument of a list of labels for the ticks. If called with no arguments, the function returns a list of the current tick positions and labels instead.

The spines of a Matplotlib plot are the black border lines around the plot, with the left and bottom ones also being used as the axis lines. To access the spines of a plot, call `ax.spines[side]`, where `ax` is an `Axes` object and `side` is `'top'`, `'bottom'`, `'left'`, or `'right'`. Then, functions can be called on the `Spine` object to configure it.

The function `spine.set_position()` has several ways to specify the position. The two simplest are with the arguments `'center'` and `'zero'`, which place the spine in the center of the subplot or at an x - or y -coordinate of zero, respectively. The others are passed as a tuple `(position_type, amount)`:

- `'data'`: place the spine at an x - or y -coordinate equal to `amount`.
- `'axes'`: place the spine at the specified `Axes` coordinate, where 0 corresponds to the bottom or left of the subplot, and 1 corresponds to the top or right edge of the subplot.
- `'outward'`: places the spine `amount` pixels outward from the edge of the plot area. A negative value can be used to move it inwards instead.

`spine.set_color()` accepts any of the color formats Matplotlib supports. Alternately, using `set_color('none')` will make the spine not be visible. `spine.set_visible()` can also be used for this purpose.

The following example adjusts the ticks and spine positions to improve the readability of a plot of $\sin(x)$. The result is shown in Figure B.2.

```
>>> x = np.linspace(0,2*np.pi,150)
>>> plt.plot(x, np.sin(x))
>>> plt.title(r"$y=\sin(x)$")

#Set the ticks to multiples of pi/2, make nice labels
>>> ticks = np.pi / 2 * np.array([0,1,2,3,4])
```

```

>>> tick_labels = ["$0$", r"$\frac{\pi}{2}$", r"$\pi$", r"$\frac{3\pi}{2}$",
...                 r"$2\pi$"]
>>> plt.xticks(ticks, tick_labels)

#Move the bottom spine to zero, remove the top and right ones
>>> ax = plt.gca()
>>> ax.spines['bottom'].set_position('zero')
>>> ax.spines['right'].set_color('none')
>>> ax.spines['top'].set_color('none')

>>> plt.show()

```

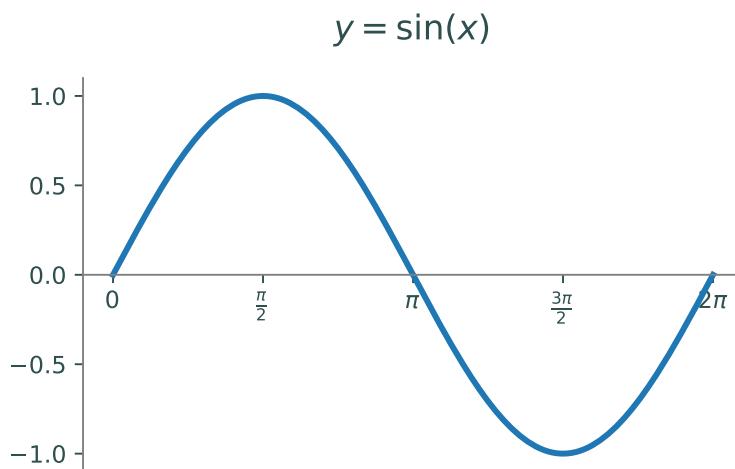

Figure B.2: Plot of $y = \sin(x)$ with axes modified for clarity

Plot Layout

The position and spacing of all subplots within a figure can be modified using the function `plt.subplots_adjust()`. This function accepts up to six keyword arguments that change different aspects of the spacing. `left`, `right`, `top`, and `bottom` are used to adjust the rectangle around all of the subplots. In the coordinates used, 0 corresponds to the bottom or left edge of the figure, and 1 corresponds to the top or right edge of the figure. `hspace` and `wspace` set the vertical and horizontal spacing, respectively, between subplots. The units for these are in fractions of the average height and width of all subplots in the figure. If more fine control is desired, the position of individual `Axes` objects can also be changed using `ax.get_position()` and `ax.set_position()`.

The size of the figure can be configured using the `figsize` argument when creating a figure:

```
>>> plt.figure(figsize=(12,8))
```

Note that many environments will scale the figure to fill the available space. Even so, changing the figure size can still be used to change the aspect ratio as well as the relative size of plot elements.

The following example uses `subplots_adjust()` to create space for a legend outside of the plotting space. The result is shown in Figure B.3.

```
#Generate data
>>> x1 = np.random.normal(-1, 1.0, size=60)
>>> y1 = np.random.normal(-1, 1.5, size=60)
>>> x2 = np.random.normal(2.0, 1.0, size=60)
>>> y2 = np.random.normal(-1.5, 1.5, size=60)
>>> x3 = np.random.normal(0.5, 1.5, size=60)
>>> y3 = np.random.normal(2.5, 1.5, size=60)

#Make the figure wider
>>> fig = plt.figure(figsize=(5,3))

#Plot the data
>>> plt.plot(x1, y1, 'r.', label="Dataset 1")
>>> plt.plot(x2, y2, 'g.', label="Dataset 2")
>>> plt.plot(x3, y3, 'b.', label="Dataset 3")

#Create a legend to the left of the plot
>>> lspace = 0.35
>>> plt.subplots_adjust(left=lspace)
#Put the legend at the left edge of the figure
>>> plt.legend(loc=(-lspace/(1-lspace),0.6))
>>> plt.show()
```

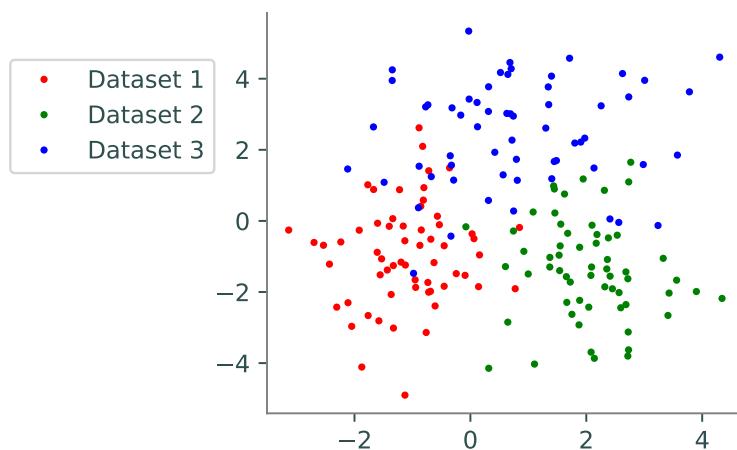

Figure B.3: Example of repositioning axes.

Colors

The color that a plotting function uses is specified by either the `c` or `color` keyword arguments; for most functions, these can be used interchangeably. There are many ways to specify colors. The most simple is to use one of the basic colors, listed in Table B.3. Colors can also be specified using an RGB tuple such as `(0.0, 0.4, 1.0)`, a hex string such as `"#0000FF"`, or a CSS color name like `"DarkOliveGreen"` or `"FireBrick"`. A full list of named colors that Matplotlib supports can be found at https://matplotlib.org/stable/gallery/color/named_colors.html. If no color is specified for a plot, Matplotlib automatically assigns it one from the default color cycle.

Code	Color	Code	Color
'b'	blue	'y'	yellow
'g'	green	'k'	black
'r'	red	'w'	white
'c'	cyan	'CO' - 'C9'	Default colors
'm'	magenta		

Table B.3: Basic colors available in Matplotlib

Plotting functions also accept an `alpha` keyword argument, which can be used to set the transparency. A value of 1.0 corresponds to fully opaque, and 0.0 corresponds to fully transparent.

The following example demonstrates different ways of specifying colors:

```
#Using a basic color
>>> plt.plot(x, y, 'r')
#Using a hexadecimal string
>>> plt.plot(x, y, color='FF0080')
#Using an RGB tuple
>>> plt.plot(x, y, color=(1, 0.5, 0))
#Using a named color
>>> plt.plot(x, y, color='navy')
```

Colormaps

Certain plotting functions, such as heatmaps and contour plots, accept a colormap rather than a single color. A full list of colormaps available in Matplotlib can be found at https://matplotlib.org/stable/gallery/color/colormap_reference.html. Some of the more commonly used ones are `"viridis"`, `"magma"`, and `"coolwarm"`. A colorbar can be added by calling `plt.colorbar()` after creating the plot.

Sometimes, using a logarithmic scale for the coloring is more informative. To do this, pass a `matplotlib.colors.LogNorm` object as the `norm` keyword argument:

```
# Create a heatmap with logarithmic color scaling
>>> from matplotlib.colors import LogNorm
>>> plt.pcolormesh(X, Y, Z, cmap='viridis', norm=LogNorm())
```

Function	Description	Usage
<code>annotate()</code>	adds a commentary at a given point on the plot	<code>annotate('text',(x,y))</code>
<code>arrow()</code>	draws an arrow from a given point on the plot	<code>arrow(x,y,dx,dy)</code>
<code>colorbar()</code>	Create a colorbar	<code>colorbar()</code>
<code>legend()</code>	Place a legend in the plot	<code>legend(loc='best')</code>
<code>text()</code>	Add text at a given position on the plot	<code>text(x,y,'text')</code>
<code>title()</code>	Add a title to the plot	<code>title('text')</code>
<code>suptitle()</code>	Add a title to the figure	<code>suptitle('text')</code>
<code>xlabel()</code>	Add a label to the x -axis	<code>xlabel('text')</code>
<code>ylabel()</code>	Add a label to the y -axis	<code>ylabel('text')</code>

Table B.4: Text and annotation functions in Matplotlib

Text and Annotations

Matplotlib has several ways to add text and other annotations to a plot, some of which are listed in Table B.4. The color and size of the text in most of these functions can be adjusted with the `color` and `fontsize` keyword arguments.

Matplotlib also supports formatting text with L^AT_EX, a system for creating technical documents.¹ To do so, use an `r` before the string quotation mark and surround the text with dollar signs. This is particularly useful when the text contains a mathematical expression. For example, the following line of code will make the title of the plot be $\frac{1}{2} \sin(x^2)$:

```
>>> plt.title(r"\frac{1}{2}\sin(x^2)")
```

The function `legend()` can be used to add a legend to a plot. Its optional `loc` keyword argument specifies where to place the legend within the subplot. It defaults to `'best'`, which will cause Matplotlib to place it in whichever location overlaps with the fewest drawn objects. The other locations this function accepts are `'upper right'`, `'upper left'`, `'lower left'`, `'lower right'`, `'center left'`, `'center right'`, `'lower center'`, `'upper center'`, and `'center'`. Alternately, a tuple of (x,y) can be passed as this argument, and the bottom-left corner of the legend will be placed at that location. The point $(0,0)$ corresponds to the bottom-left of the current subplot, and $(1,1)$ corresponds to the top-right. This can be used to place the legend outside of the subplot, although care should be taken that it does not go outside the figure, which may require manually repositioning the subplots.

The labels the legend uses for each curve or scatterplot are specified with the `label` keyword argument when plotting the object. Note that `legend()` can also be called with non-keyword arguments to set the labels, although it is less confusing to set them when plotting.

The following example demonstrates creating a legend:

```
>>> x = np.linspace(0,2*np.pi,250)

# Plot sin(x), cos(x), and -sin(x)
# The label argument will be used as its label in the legend.
>>> plt.plot(x, np.sin(x), 'r', label=r'\sin(x)')
>>> plt.plot(x, np.cos(x), 'g', label=r'\cos(x)')
>>> plt.plot(x, -np.sin(x), 'b', label=r'-\sin(x)')
```

¹See <http://www.latex-project.org/> for more information.

```
# Create the legend
>>> plt.legend()
```

Line and marker styles

Matplotlib supports a large number of line and marker styles for line and scatter plots, which are listed in Table B.5.

character	description	character	description
-	solid line style	3	tri_left marker
--	dashed line style	4	tri_right marker
-.	dash-dot line style	s	square marker
:	dotted line style	p	pentagon marker
.	point marker	*	star marker
,	pixel marker	h	hexagon1 marker
o	circle marker	H	hexagon2 marker
v	triangle_down marker	+	plus marker
^	triangle_up marker	x	x marker
<	triangle_left marker	D	diamond marker
>	triangle_right marker	d	thin_diamond marker
1	tri_down marker		vline marker
2	tri_up marker	_	hline marker

Table B.5: Available line and marker styles in Matplotlib.

The function `plot()` has several ways to specify this argument; the simplest is to pass it as the third positional argument. The `marker` and `linestyle` keyword arguments can also be used. The size of these can be modified using `markersize` and `linewidth`. Note that by specifying a marker style but no line style, `plot()` can be used to make a scatter plot. It is also possible to use both a marker style and a line style. To set the marker using `scatter()`, use the `marker` keyword argument, with `s` being used to change the size.

The following code demonstrates specifying marker and line styles. The results are shown in Figure B.4.

```
#Use dashed lines:
>>> plt.plot(x, y, '--')
#Use only dots:
>>> plt.plot(x, y, '.')
#Use dots with a normal line:
>>> plt.plot(x, y, '.-')
#scatter() uses the marker keyword:
>>> plt.scatter(x, y, marker='+')

#With plot(), the color to use can also be specified in the same string.
#Order usually doesn't matter.
#Use red dots:
>>> plt.plot(x, y, '.r')
```

```
#Equivalent:  
>>> plt.plot(x, y, 'r.')  
  
#To change the size:  
>>> plt.plot(x, y, 'v-', linewidth=1, markersize=15)  
>>> plt.scatter(x, y, marker='+', s=12)
```

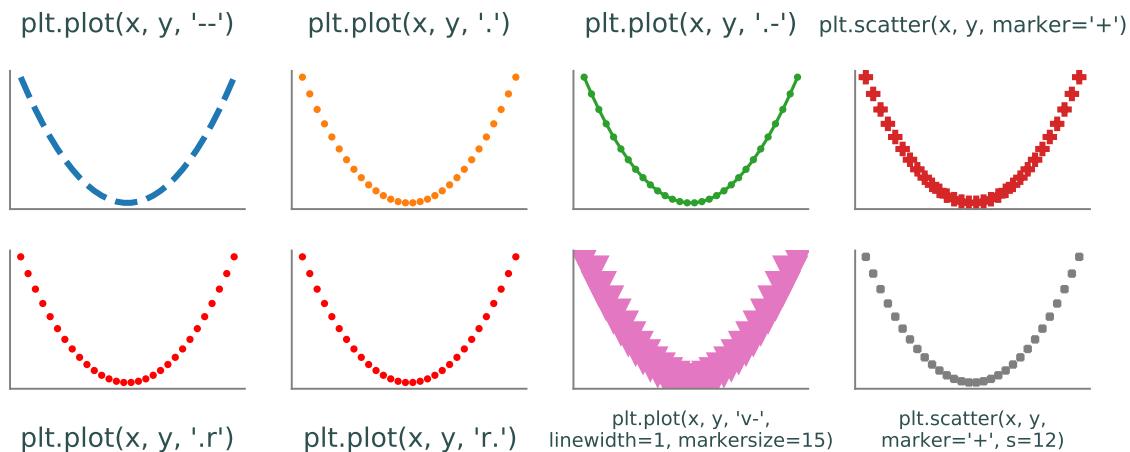

Figure B.4: Examples of setting line and marker styles.

Plot Types

Matplotlib has functions for creating many different types of plots, many of which are listed in Table B.6. This section gives details on using certain groups of these functions.

Function	Description	Usage
<code>bar</code>	makes a bar graph	<code>bar(x,height)</code>
<code>barh</code>	makes a horizontal bar graph	<code>barh(y,width)</code>
<code>boxplots</code>	makes one or more boxplots	<code>boxplots(data)</code>
<code>contour</code>	makes a contour plot	<code>contour(X,Y,Z)</code>
<code>contourf</code>	makes a filled contour plot	<code>contourf(X,Y,Z)</code>
<code>imshow</code>	shows an image	<code>imshow(image)</code>
<code>fill</code>	plots lines with shading under the curve	<code>fill(x,y)</code>
<code>fill_between</code>	plots lines with shading between two given y values	<code>fill_between(x,y1, y2=0)</code>
<code>hexbin</code>	creates a hexbin plot	<code>hexbin(x,y)</code>
<code>hist</code>	plots a histogram from data	<code>hist(data)</code>
<code>pcolormesh</code>	makes a heatmap	<code>pcolormesh(X,Y,Z)</code>
<code>pie</code>	makes a pie chart	<code>pie(x)</code>
<code>plot</code>	plots lines and data on standard axes	<code>plot(x,y)</code>
<code>plot_surface</code>	plot a surface in 3-D space	<code>plot_surface(X,Y,Z)</code>
<code>polar</code>	plots lines and data on polar axes	<code>polar(theta,r)</code>
<code>loglog</code>	plots lines and data on logarithmic x and y axes	<code>loglog(x,y)</code>
<code>scatter</code>	plots data in a scatterplot	<code>scatter(x,y)</code>
<code>semilogx</code>	plots lines and data with a log scaled x axis	<code>semilogx(x,y)</code>
<code>semilogy</code>	plots lines and data with a log scaled y axis	<code>semilogy(x,y)</code>
<code>specgram</code>	makes a spectrogram from data	<code>specgram(x)</code>
<code>spy</code>	plots the sparsity pattern of a 2D array	<code>spy(Z)</code>
<code>triplot</code>	plots triangulation between given points	<code>triplot(x,y)</code>

Table B.6: Some basic plotting functions in Matplotlib.

Line plots

Line plots, the most basic type of plot, are created with the `plot()` function. It accepts two lists of x- and y-values to plot, and optionally a third argument of a string of any combination of the color, line style, and marker style. Note that this method only works with the single-character color codes; to use other colors, use the `color` argument. By specifying only a marker style, this function can also be used to create scatterplots.

There are a number of functions that do essentially the same thing as `plot()` but also change the axis scaling, including `loglog()`, `semilogx()`, `semilogy()`, and `polar`. Each of these functions is used in the same manner as `plot()`, and has identical syntax.

Bar Plots

Bar plots are a way to graph categorical data in an effective way. They are made using the `bar()` function. The most important arguments are the first two that provide the data, `x` and `height`. The first argument is a list of values for each bar, either categorical or numerical; the second argument is a list of numerical values corresponding to the height of each bar. There are other parameters that may be included as well. The `width` argument adjusts the bar widths; this can be done by choosing a single value for all of the bars, or an array to give each bar a unique width. Further, the argument `bottom` allows one to specify where each bar begins on the y-axis. Lastly, the `align` argument can be set to 'center' or 'edge' to align as desired on the x-axis. As with all plots, you can use the `color` keyword to specify any color of your choice. If you desire to make a horizontal bar graph, the syntax follows similarly using the function `barh()`, but with argument names `y`, `width`, `height` and `align`.

Box Plots

A box plot is a way to visualize some simple statistics of a dataset. It plots the minimum, maximum, and median along with the first and third quartiles of the data. This is done by using `boxplot()` with an array of data as the argument. Matplotlib allows you to enter either a one dimensional array for a single box plot, or a 2-dimensional array where it will plot a box plot for each column of the data in the array. Box plots default to having a vertical orientation but can be easily laid out horizontally by setting `vert=False`.

Scatter and hexbin plots

Scatterplots can be created using either `plot()` or `scatter()`. Generally, it is simpler to use `plot()`, although there are some cases where `scatter()` is better. In particular, `scatter()` allows changing the color and size of individual points within a single call to the function. This is done by passing a list of colors or sizes to the `c` or `s` arguments, respectively.

Hexbin plots are an alternative to scatterplots that show the concentration of data in regions rather than the individual points. They can be created with the function `hexbin()`. Like `plot()` and `scatter()`, this function accepts two lists of x- and y-coordinates.

Heatmaps and contour plots

Heatmaps and contour plots are used to visualize 3-D surfaces and complex-valued functions on a flat space. Heatmaps are created using the `pcolormesh()` function. Contour plots are created using `contour()` or `contourf()`, with the latter creating a filled contour plot.

Each of these functions accepts the x-, y-, and z-coordinates as a mesh grid, or 2-D array. To create these, use the function `np.meshgrid()`:

```
>>> x = np.linspace(0,1,100)
>>> y = np.linspace(0,1,80)
>>> X, Y = np.meshgrid(x, y)
```

The z-coordinate can then be computed using the x and y mesh grids.

Note that each of these functions can accept a colormap, using the `cmap` parameter. These plots are sometimes more informative with a logarithmic color scale, which can be used by passing a `matplotlib.colors.LogNorm` object in the `norm` parameter of these functions.

With `pcolormesh()`, it is also necessary to pass `shading='auto'` or `shading='nearest'` to avoid a deprecation error.

The following example demonstrates creating heatmaps and contour plots, using a graph of $z = (x^2 + y) \sin(y)$. The results is shown in Figure B.5

```
>>> from matplotlib.colors import LogNorm

>>> x = np.linspace(-3,3,100)
>>> y = np.linspace(-3,3,100)
>>> X, Y = np.meshgrid(x, y)
>>> Z = (X**2+Y)*np.sin(Y)

#Heatmap
>>> plt.subplot(1,3,1)
```

```

>>> plt.pcolormesh(X, Y, Z, cmap='viridis', shading='nearest')
>>> plt.title("Heatmap")

#Contour
>>> plt.subplot(1,3,2)
>>> plt.contour(X, Y, Z, cmap='magma')
>>> plt.title("Contour plot")

#Filled contour
>>> plt.subplot(1,3,3)
>>> plt.contourf(X, Y, Z, cmap='coolwarm')
>>> plt.title("Filled contour plot")
>>> plt.colorbar()

>>> plt.show()

```

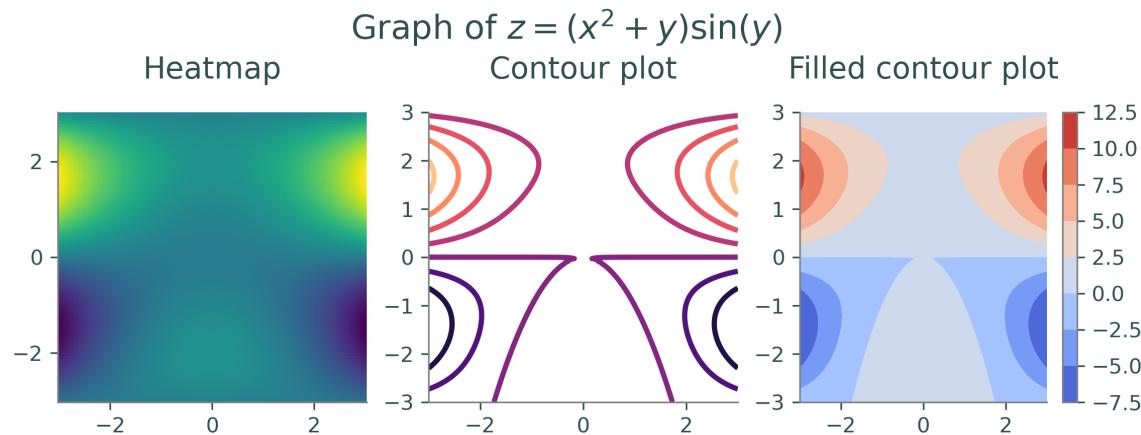

Figure B.5: Example of heatmaps and contour plots.

Showing images

The function `imshow()` is used for showing an image in a plot, and can be used on either grayscale or color images. This function accepts a 2-D $n \times m$ array for a grayscale image, or a 3-D $n \times m \times 3$ array for a color image. If using a grayscale image, you also need to specify `cmap='gray'`, or it will be colored incorrectly.

It is best to also use `axis('equal')` alongside `imshow()`, or the image will most likely be stretched. This function also works best if the images values are in the range [0, 1]. Some ways to load images will format their values as integers from 0 to 255, in which case the values in the image array should be scaled before using `imshow()`.

3-D Plotting

Matplotlib can be used to plot curves and surfaces in 3-D space. In order to use 3-D plotting, you need to run the following line:

```
>>> from mpl_toolkits.plot3d import Axes3D
```

The argument `projection='3d'` also must be specified when creating the subplot for the 3-D object:

```
>>> plt.subplot(1,1,1, projection='3d')
```

Curves can be plotted in 3-D space using `plot()`, by passing in three lists of x-, y-, and z-coordinates. Surfaces can be plotted using `ax.plot_surface()`. This function can be used similar to creating contour plots and heatmaps, by obtaining meshes of x- and y- coordinates from `np.meshgrid()` and using those to produce the z-axis. More generally, any three 2-D arrays of meshes corresponding to x-, y-, and z-coordinates can be used. Note that it is necessary to call this function from an Axes object.

The following example demonstrates creating 3-D plots. The results are shown in Figure B.6.

```
#Create a plot of a parametric curve
ax = plt.subplot(1,3,1, projection='3d')
t = np.linspace(0, 4*np.pi, 160)
x = np.cos(t)
y = np.sin(t)
z = t / np.pi
plt.plot(x, y, z, color='b')
plt.title("Helix curve")

#Create a surface plot from np.meshgrid
ax = plt.subplot(1,3,2, projection='3d')
x = np.linspace(-1,1,80)
y = np.linspace(-1,1,80)
X, Y = np.meshgrid(x, y)
Z = X**2 - Y**2
ax.plot_surface(X, Y, Z, color='g')
plt.title(r"Hyperboloid")

#Create a surface plot less directly
ax = plt.subplot(1,3,3, projection='3d')
theta = np.linspace(-np.pi,np.pi,80)
rho = np.linspace(-np.pi/2,np.pi/2,40)
Theta, Rho = np.meshgrid(theta, rho)
X = np.cos(Theta) * np.cos(Rho)
Y = np.sin(Theta) * np.cos(Rho)
Z = np.sin(Rho)
ax.plot_surface(X, Y, Z, color='r')
plt.title(r"Sphere")

plt.show()
```

Additional Resources

rcParams

The default plotting parameters of Matplotlib can be set individually and with more fine control than styles by using `rcParams`. `rcParams` is a dictionary that can be accessed as either `plt.rcParams` or `matplotlib.rcParams`.

For instance, the resolution of plots can be changed via the "`figure.dpi`" parameter:

```
>>> plt.rcParams["figure.dpi"] = 600
```

A list of parameters that can set via `rcParams` can be found at https://matplotlib.org/stable/api/matplotlib_configuration_api.html#matplotlib.RcParams.

Animations

Matplotlib has capabilities for creating animated plots. The Animations lab in Volume 4 has detailed instructions on how to do so.

Matplotlib gallery and tutorials

The Matplotlib documentation has a number of tutorials, found at <https://matplotlib.org/stable/tutorials/index.html>. It also has a large gallery of examples, found at <https://matplotlib.org/stable/gallery/index.html>. Both of these are excellent sources of additional information about ways to use and customize Matplotlib.
